Introduction

In geophysical terms, China is a "data rich" country. However it is often very difficult for Western scientists to access the available information or identify individuals responsible for program development. The USGS has largely bypassed this bottleneck by virtue of more than two decades of collaborative research based on an official Protocol Agreement.

Geologic and geophysical data are collected by many agencies in China, including the Ministry of Geology and Natural Resources (MGNR), Chinese Academy of Sciences, and the State Seismological Bureau (SSB). The USGS cooperation has primarily been with the SSB, and is based on a formal Protocol established in 1976, which undergoes an annual review. More limited cooperation has taken place with the MGNR. At present the USGS maintains about a dozen cooperative projects with the SSB. One conspicuously successful aspect of the USGS program with the SSB is the operation of the 11-station Chinese Digital Seismographic Network (CDSN), which feeds data to US investigators. The aspect of the USGS program involving seismological studies of the crust and uppermost mantle of China has also long been very active.

The USGS emphasis on cooperation with the SSB is fortuitous in view of the fact that the Central Government decided during the April, 1998, Party Congress to reduce the number of State employees and number of Ministries by more than half. During this shuffle the MGNR will be reduced in size and placed under the administration of the new Ministry of Land and Resources. The Chinese Academy of Sciences will see many changes, including the reduction and merging of the Institute of Geology and Institute of Geophysics into an organization that has not yet been identified. The SSB, which is not administered by any Ministry, will be strengthened and will almost certainly emerge as the leading organization for geophysics within China. The full scope of its responsibilities related to CTBT research is not well known.

This report is focused on the crustal structure of China. Completed research is summarized in seven chapters. The location of the seven study areas is presented in Figure 1. Many of the results reported here have not been published, and are not available elsewhere. No attempt is made in this introduction to summarize these seven chapters; the abstracts serve this purpose.

Milestones and Deliverables

1. Compilation of Geophysical Data and Results:

New geophysical interpretations and/or seismological data have been provided by the Chinese for the seven study areas in Figure 1. In five of the seven study areas, USGS staff have participated in the analysis of the data and report preparation, most of which was completed in our Menlo Park, California, office. Thus, all results are available in digital form. Of greatest significance are: (1) the long-range "Geoscience Transect" extending from NW China, across the entire country, to the coast opposite the Island of Taiwan (Chapters 2.1 and 2.2); (2) profile data from East-central China near Wuhan (Chapter 2.3); and (3) network data from SW China (Yunnan and Schezwan Provinces; Chapter 2.6); and (4) a new synthesis of the crustal structure of China (Chapter 2.7).

In addition, Walter D. Mooney served as the English language editor of the Atlas of Geophysics in China (Geological Publishing House, 1996), and copies of this book have been provided by the Chinese to Dr. Mooney, who has passed them on to Dr. W. Brunish and Dr. G. Randall, LANL (New Mexico). For reasons that are not clear, it is very difficult to obtain this book (priced at \$200 US per copy), even in China.

2. Exchange of High-level Scientists and Administrators:

High-level Chinese scientists have been sponsored at the USGS-Menlo Park, thereby providing access to data, interpretations, and information regarding future research plans. In 1997/98 we sponsored the Deputy Director of the SSB (Prof. He), the Director of International Cooperation, (Madame Wang Hongzhen), the Director and Vice-Director of the Institute of Geophysics (Prof. Chen Yuntai and Wang Chunyong, respectively), the Bureau Chief of the SSB in Jinjiang Province, and six other important administrators. It is on the basis of such visits that American investigators can reasonably expect access to Chinese interpretations, and to establish personal contacts as the need arises. Because of the size and diversity of Chinese geophysical research institutions, ranging from the centralized SSB offices in Beijing to small, but active Provincial Bureaus, it is difficult to anticipate opportunities to gather data relevant to CTBT monitoring. Openness and visibility within the Chinese scientific community is critical.

3. Workshop Plans (November, 1998)

The SSB Director of International Relations has agreed to sponsor a workshop entitled "Geodynamics and Earthquake Hazards in China", to be held in Shanghai in November (date changed from July). Prof. Francis Wu, Dr. Leonard E. Johnson, and Dr. Mooney will be co-convenors on the American side, and will nominate participants. This workshop was initiated on the American side to broaden bilateral discussions.

4. Invitation to participate in a major field program, West-central China, 1998

American investigators has been invited to participate in a major explosion-seismology field investigation to take place in West-central China in June, 1999. The Project Chief, Prof. Wang Chunyong, visited Menlo Park for three months in 1998 to discuss this and related topics. This project will involve 12 large chemical shots fired in water bodies and borehole. The profile is located at a latitude of 30° N., from 95° to 105° E (east flank of the Tibetan Plateau. The nature and extent of potential American participation is still under discussion.

5. Coordination of field programs, 1997/1998

We have fostered US participation (lead by Prof. Francis Wu) in an SSB project that includes passive seismic recording in NE China, on the border with North Korea. US participation in this project negotiated "on the spot" at the October, 1997, US-SSB Coordinators Meeting in Beijing attended by Mooney and Wu. Dr. Mooney and Dr. L.E. Johnson (NSF) meet on an annual basis for a four day US-PRC Coordinator's meeting to negotiate the list of approved activities between the SSB and America for the coming year. The next coordinator's meeting will be held in September, 1998, at the USGS Seismological Laboratory in Albuquerque, New Mexico. The site was chosen in part to facilitate potential interaction with the staff of the Los Alamos National Laboratory. It is proposed that potential American participation in a large-scale seismic experiment in West-central China (item 4) be negotiated at this important September meeting.

Conclusions

We achieved all of the goals we set out for this activity, and have also capitalized on some unexpected opportunities. We continue to have a good working relationship with the leading geophysical organization in China, the State Seismological Bureau (SSB), and with the Ministry of Geology and Mineral Resources (MGMR). This relationship has yielded new, unpublished data and interpretations that have allowed us to characterize the properties of the crust and uppermost mantle of China. This relationship has also provided American scientists with access to scientific decision makers, and given us prior knowledge of major scientific initiatives of interest to CTBT monitoring research.

ABSTRACT

We present a new crustal cross-section across northwest China based on a seismic refraction profile and geological mapping. The 1100 km-long seismic refraction profile, located on the northwesternmost part of the Geoscience Transect from Taiwan to Altai, crosses the southern margin of the Altai block, the Junggar Accretional Belt, the Tianshan Accretional Belt and the Tarim Platform. P- and S-wave seismic data acquired along this profile were used to model both the crustal velocity structure and Poisson's ratio in a section through the crust and upper mantle. The largest difference in crustal thickness is located at the northern end of the profile, where over a distance of <400 km, it varies from 54 km thick under the Altai block to 46 km thick under the Junggar Basin. On the southern side of the basin, the crustal thickness increases to about 49 km, and it remains this thickness over the rest of the southern portion of the profile, with only slight variation. Higher velocity crust with Poisson's ratio of $\sigma=0.25-0.28$ ($V_p/V_s=1.73-1.81$), observed below the Junggar Accretional Belt, may imply either a mafic crystalline Precambrian basement or imbricated Paleozoic accretionary belt, whereas the lower Poisson's ratios $\sigma=0.25-0.26$ ($V_p/V_s=1.73-1.76$), modeled through the crust in the Tianshan province, may imply a more granitic composition. The upper and middle crust of the Tarim Platform has a Poisson's ratio of around 0.25 ($V_p/V_s=1.73$), with lower average P-wave velocities than the Tianshan accretional belt (6.0-6.3 km/s and 6.1-6.5 km/s, respectively), suggesting

highly fractured units in the Tarim Platform. A mid-crustal low-velocity layer ($V_p=5.9$ km/s, $\sigma=0.25$) straddles the Tianshan-Tarim boundary and is underlain by a lower crust, suggesting that Kushui Fault probably indicates the boundary between Tianshan fold belt and Tarim platform. Observed P_n velocities seem to vary with tectonic province as we observed P_n velocities of 7.7~7.8 km/s between Bogdashaan and Tianshan and 7.9~8.0 km/s below the Altai fold belt and Tarim Platform.

INTRODUCTION

In 1988, as part of the Geoscience Transect from Taiwan to Altai (GTTA), the Chinese Ministry of Geology and Mineral Resources (MGMR) collected 3-component seismic data along a 1100 km-long seismic refraction profile across northwest China (Fig. 1). The goal of this project was to gain a better understanding of the deep crustal structure beneath different tectonic provinces in the area, and to provide crustal data for mineral resource development (Xu and Wang 1991; Wang 1992; Yuan, Zuo, and Zhang 1992; Yuan, Zuo, and Zhang 1992 and 1994).

Some information regarding the crustal velocity structure has already been compiled for this area using tomography, including body and surface waves from earthquake data (Futian et al. 1989; Teng et al. 1992, 1994; Feng et al. 1980; H. Mahdi and G. L. Pavlis, 1998). In recent years, advances in processing techniques for 3-component data have enabled us to model both the P- and S-wave velocity structure from the data collected along the profile, and to infer compositional changes within the crust and uppermost mantle from the modeled V_p/V_s or Poisson's ratios (Gajewski et al. 1990; Kosminskaya 1995; Castagna 1985; Eesley 1989; Carbonell and Smithson 1995; Krilov et al. 1995a; Holbrook et al. 1988; Holbrook, W.D. Mooney, and Christensen 1992).

GENERAL TECTONICS OF NORTHWEST CHINA

Like many other continental regions, the geology of northwestern China consists of Precambrian cratons surrounded by accreted terranes that make up fold belts of various ages. Accretion probably commenced at different times around each craton, ranging from the Proterozoic to the Early Paleozoic (Fig. 1). The tectonic evolution of northwest China

is complex, and includes evidence of Late Paleozoic consolidation that was modified by Mesozoic foreland basin development, followed by Cenozoic uplift produced by compression and strike slip faulting (Berzin, Buslov, and Dobretsov 1991; Sengor, Natalin, and Burtman 1993).

The important cratonic elements of China are the Sino-Korean and Yangtze cratons and, to the west, the Tarim Platform (Fig. 1) (Zhang, Liou, and Coleman 1984). Equally important is the Siberian craton far to the north with its extensive Early to Late Paleozoic accretional belts now outcropping in the Altai Mountains.

The Sino-Korean craton forms a roughly triangular shape which includes Northern China, North Korea, and South Korea (Fig. 1). The nucleus of the craton is considered to have formed 3.0 Ga followed by the Wutai orogeny at 2.0 Ga with final consolidation at 1.7 Ga. From Late Proterozoic to Ordovician time, a thick passive margin sedimentary sequence was deposited. Late Ordovician to Early Carboniferous sediments are generally missing. Permian molasse and coal measures mark the final closure between the Sino-Korean and Siberian cratons (Zhang, Liou, and Coleman 1984). The Yangtze craton formed in the period between Late Archean and the Late Proterozoic with final consolidation during the Yangtze orogeny (~ 825 Ma) (Zhang 1985; Chang et al. 1994). The Yangtze and Sino Korean cratons were separated by the eastern Paleoasian Ocean (sometimes called Paleo-Tethys) until they collided to form the Qinling accretional belt in the Early Mesozoic (Chang et al. 1994).

The Tarim platform is a relatively small block with many internal basement units characterized by a thick cover of passive margin sediments dating from Late Proterozoic to Cenozoic (Ren et al. 1987). The Yili block forms a very small triangular wedge whose basement is Proterozoic with a similar history to that of the Tarim platform (Zhou, 1997). Present day convergent strike-slip faults have imbedded the Yili Block into the Tianshan (Fig. 1). The consolidation of the Tarim platform, the Yili Block, and the Tianshan accretional zones began in the Carboniferous. The change from marine to lacustrine deposits in the Junggar and Turpan basins was accompanied by collisional and intruding post collisional granites during the Late Carboniferous and Permian marking the closure of the western Paleoasian Ocean (Carroll et al. 1995). To the east, the Yangtze and Sino-

Korean cratons with their accreted margins came together in the Early Mesozoic forming the Qinling accretional system (Zhou and Graham,1996). Antecedent to these earlier amalgamations was the Himalayan collision (commencing ca 45 Ma), that has been marked by 2000 km of convergence between India and Eurasia, some of which occurs in the previously described consolidation of Central Asia (Northwest China) (Powell and Conaghan,1973). Basin analyses and fission track studies of the Chinese Tianshan indicates that on set of rapid uplift in the Mid-Tertiary, that continues up to the present, can be related to the Himalayan collision (Carroll et al.,1995; Zhou,1997). There is good evidence that at least some of the convergence can be accounted for by strike slip motion and compression (folding) across the Altai Mountains to the Kunlun Mountains (Zhou and Graham 1996).

GEOLOGICAL SETTING

The north-south transect cuts eight distinct blocks at high angles (Fig. 2). Major faults and sutures dividing represent terrane boundaries. Some of these boundaries are still active and have been the locus of major historic earthquakes, while others mark the tectonic zones of Paleozoic and Mesozoic continental growth.

The Altai Block

North of the Ertysch fault, the Altai block (Fig. 2) includes an Early Paleozoic accretionary wedge nearly 12 km thick, consisting of metamorphosed sandstone, shales, and minor limestones. Intercalated within these sedimentary sequences are mid-Paleozoic island arc volcanics and calc-alkaline intrusives. Paleozoic low P and high T metamorphism affected all of these rocks with intensity decreasing from north to south (Cunningham et al., 1996a; Cunningham et al., 1996b; Qu and He, 1993; Dong, 1993; Windley et al., 1990) (Fig. 2). The question of the existence of older basement in the Altai is not yet resolved, but the presence of gneissic rocks along the southern border are considered as Precambrian basement (Chang, Ying, and Coleman, 1996). Windley et al. (1994) suggest that these gneisses may represent Precambrian-Early Paleozoic accreted

fragments. Berzin et al. (1994) show the Altai block as a micro-continent with possible Precambrian basement (Bibkova et al., 1992).

Junggar Accretional Belt

The Junggar Accretional Belt between the Ertysch and Kelameli faults consists mainly of accreted Devonian and Carboniferous sediments and volcanics with only scattered Ordovician and Silurian rocks. Dismembered ophiolites are concentrated along the Ertysch, Kelimali and Almanti faults (Fig. 2). Associated radiolaria cherts in this zone range from Devonian to Carboniferous. These ophiolites and cherts occur mainly in a serpentinite matrix melange indicating continued subduction and accretion from Early -Middle Devonian to Early Carboniferous. Calc-alkaline intrusions of this time period within the Altai and Junggar accretionary belt are derived from north-directed subduction. The final closure along the Junggar accretional belt is marked by abundant post collisional granite intruding both the Junggar belt and extend northward into the Altai block (Coleman, 1989).

Junggar Basin

The Junggar basin is deposited on a basement similar to the Junggar accretional belt. The basin is triangular in shape, thickening gradually from north to south, and becoming extremely deep along the Bogda island arc mountain front (Fig. 2). The basal upper Permian deposits of the Junggar Basin are non-marine and deposited within a subsiding foreland basin (Carroll et al., 1990). Plate tectonic reconstructions suggest that the basement for the Junggar Basin consists of incompletely subducted mid-Carboniferous ocean crust now imbricated with sedimentary trench volcanic arc deposits.

Bogdashaan Volcanic Arc

The Carboniferous Bogdashaan volcanic arc, south of the Junggar Basin, developed by southward subduction and extension within the earlier accreted Paleozoic and Precambrian Tianshan blocks. The core of the arc appears to be centered in the Bogdashaan where thick sections of Carboniferous submarine pyroclastics and basal-andesite flows

extend north and south across the present Junggar and Turpan Basins (Coleman, 1989) (Fig. 2). To the west of the Bogdashan in the Borohorashan, the Carboniferous volcanics rest unconformably on Early Paleozoic folded accretional complex of trench sediments and dismembered ophiolite. Evidence for a Precambrian basement underlying these Carboniferous volcanics is not seen along the northern front of the Bogdashan (Ren et al., 1987). Permian lacustrine deposits and their overlying granitic-rich clastics are similar in both basins suggesting that an Andean-type arc did not separate the Turpan and Junggar Basin at this time (Greene et al., 1997).

Turpan - Hami Basin

The Turpan-Hami Basin depositional sequences are similar to those in the Junggar Basin and consist of basal Carboniferous andesitic volcanics overlain by Permian lacustrine mudstones interlayered continental fluvial and volcanic sediments. The Permian sequence is overlain by nearly 3000 m Triassic and Jurassic foreland-style continental deposits, rich in coals and lacustrine mudstones (Carroll et al., 1995; Greene et al., 1997). The Carboniferous volcanic clastic sequences exposed on the southern margins of the Turpan-Hami basin are intruded by late Paleozoic calc-alkaline granites related to the Bogdashan arc.

Tianshan

South of the Kushi Fault (also called the South Tianshan or Nicolaev Line), the Tianshan zone has been tightly compressed during the Mesozoic and Cenozoic (Fig. 2). The Central Tianshan consists of Proterozoic gneiss and schist intruded by Late Paleozoic calc-alkaline granite. These older rocks are overlain by passive margin carbonate and continental clastics of Middle and Upper Proterozoic age (Ren et al., 1987). The South Tianshan merges with the passive margin of the Tarim Platform. A Late Paleozoic subduction scenario between the Tarim and Central Tianshan has been suggested by (Allen, Windley, and Zhang, 1992) based on scraps of ophiolite within the South Tianshan fault zone. Pinching and complete wedging-out of the Central Tianshan further eastward, is related to dextral strike slip faulting and crustal subduction of the Central Tianshan

block under the north facing passive margin of the Tarim Platform (Fig. 2). Finally, the Cenozoic shortening of this area is considered to result from the collision of the Indian Craton to the south (Carroll et al., 1995; Windley et al., 1994). The Cenozoic imbrication, and thickening of the crustal section south of the Bogdashaan, was accomplished by thrusting and strike-slip faulting at the surface, submerging the Central Tianshan under the Tarim passive margin (Fig. 2). Present day strike slip motion along the Altyn Tagh wedge (Zhou and Graham, 1996) has combined to produce an unusually thick continental crust underlying the GAC transect at this longitude.

Tarim

The Tarim Platform is covered by a thick foreland sequence of continental deposits. It is nearly 10 km thick in the central portion, and thins northward to 5 km. The Altyn Tagh fault system has exposed Archean(?) basement on the southern boundary of the craton. These older rocks are cut by early Paleozoic calc-alkaline granite (Fig. 2). Beneath the sediments of the Tarim Basin, Late Proterozoic rocks floor the entire basin and exhibit some extension but the only evidence for older oceanic crust comes from the alkali-rich, rift mafic intrusives, and flows of limited exposure. The Paleozoic sequence overlying these older rocks consists of shallow marine sediments overlain by foreland-type sediments from the Mesozoic to the present (Ren et al., 1990).

Qaidam Depression - Altyn Tagh Fault

The Qaidam Depression is a Mesozoic-Cenozoic depression consisting of non-marine strata derived from lacustrine and fluvial fan deposits that contain significant coal measure (Carroll et al., 1990; Ritts, 1995). The basement consists of a late Paleozoic fold belt containing active continental margin sediments and volcanics. The whole sequence is strongly folded and is related to the east-west trending Kunlun suture containing evidence of Paleozoic convergence and development of high P - low T metamorphic rocks. The Altyn Tagh fault zone truncates these deformed E-W trending Qaidam units, juxtaposing them against the mildly deformed Tarim Platform sequences (Zhou and Graham, 1996).

SEISMIC DATA

General considerations

Seismic energy was provided by twelve shots fired in boreholes. These shots had charge sizes ranging from 1500 to 4000 kg, with a maximum offset of 300 km. The shotpoint interval ranged from 63 to 125 km, and the receiver interval was between 2 and 4 km. The entire profile is not linear, however the layout makes it possible to consider it as three nearly straight segments for purposes of interpretation.

In order to aid in the correlation of phases, reduction velocities of 6.0 km/s and 3.46 km/s were used for P- and S-waves, respectively. The time scale used for S-waves was multiplied by a factor of 0.58 in the S-wave record section so that they match the P-wave arrival times. Because a slight time shift is introduced by digital filters, the unfiltered P-wave data was used for phase correlation and traveltimes picking. In order to improve the signal-to-noise ratio for phase correlation, the S-wave data was filtered with a 0-6 Hz bandpass.

Commonly used definitions of phases, $P_g(S_g)$ actually corresponds to two traveltimes segments. The first, near the shotpoint, is a diving wave within the sedimentary layer, whereas the second is the refraction (or diving wave) from the top of basement. P_1P (S_1S), P_2P (S_2S) and P_LP (S_LS) are the reflections from the top of middle crust, lower crust and low velocity layer for P-waves (S-waves), respectively. P_mP (S_mS) is the reflection from the Moho, and P_n (S_n) is the refraction from the Moho. The typical phases mentioned above are shown in some record sections (Fig. 3).

Correlation of phases

In general, $P_g(S_g)$ is a very clear phase from which we can identify and specify the traveltimes very accurately. It contains detailed information about the upper crustal velocity structure, including sediments, or weathered layer, and basement.

The first segment of $P_g(S_g)$, corresponding to the waves propagating in the sediments or weathered layer, is well characterized because it is the first arrival within a distance of 50 km of the shotpoints. P-wave velocities observed for this segment increase

from the surface to a greater depth with stronger velocity gradient. The thicker or the lower the near-surface velocity is, the larger the P_g (S_g) time delay. In some places where sediments were thin or absent, this phase has a very small time delay, and an apparent velocity of about 6.0 km/s for P-waves (3.46 km/s for S-waves), for example, in the case of record section of SP1 (Fig. 4). However, the traveltimes of P_g (S_g) from shotpoints SP4 and SP7 (Fig. 5 and 6), which are located at the Junggar and Turpan basins respectively, are of a larger time delay. At distances greater than 50 km about from the shotpoint, P_g (S_g) becomes a refracted phase along the basement, below the sediments or weathered layer, with an apparent velocity that is usually close to or higher than the reduction velocity.

So far, we have discussed phases that occur as first arrivals near the shotpoint, which are usually easier to identify than later arrivals. The reflection P_1P (S_1S) from the top of middle crust, the next phase to arrive after P_g (S_g), has a larger amplitude than P_g (S_g). At certain distances, this phase seems to be a first arrival because the P_g (S_g) energy is too weak to be detected.

The phase P_2P (S_2S), which corresponds to the reflection from the top of the lower crust, is observed in most of the record sections, and is characterized by its arrival before the P_mP (S_mS) phase; P_2P (S_2S) intersects P_mP (S_mS) between a distance of 200 and 250 km. Despite the very great energy of the P_mP (S_mS) phase, some energy from the P_2P (S_2S) phase can be seen on the record sections as well.

In the record sections observed southwards from SP7, another phase P_LP (S_LS), can be identified in the record sections between the phases P_1P (S_1S) and P_2P (S_2S). This phase is visible in the trace-normalized record section despite its weak energy when compared to the very strong P_mP (S_mS) phase; it nearly parallels P_1P (S_1S), but has a lower average velocity. It is the phase that makes the Moho reflection a clear time delay in the related regions (Fig.3 & Fig.6). Because no obvious time delay appears for the phases before P_2P (S_2S), so the phase P_LP (S_LS) is inferred as a reflection from the top of a low velocity layer beneath this southern section of the profile.

The Moho reflection P_mP (S_mS) represents the arrival with the largest amplitude at distances larger than 100-150 km, which indicates the critical distance range for reflection

from the Moho. Due to the complex structure, especially low velocity layer within the crust below the profile, the phase P_mP (S_mS) exists in two segments with a clear time delay at some special location. This cases can be found in the record sections from shotpoint SP7 and SP10 (Fig.6 and Fig.3). In the record section of SP7, the arrivals of P_mP (S_mS) becomes later at the distance greater than 170 km around in the southern branch (about at 780 km and shotpoint SP7 is located at 602.30 km along the profile) . Meanwhile, in another record section of SP10, the traveltimes of P_mP and S_mS both delay at the distance shorter than about 200 km in northern branch (about 700 km and shotpoint SP10 is 887.70 km along the profile). These evidences indicate that the northern start point of the low velocity layer must be located at 750 km around along the profile.

P_n was observed for several shots which had receiver offsets >200 km where this phase can be seen as a first arrivals in the record sections (Fig.3, 5 and 6). The respective phase, S_n , is also visible in some S-wave sections respective to P-waves. Forward modeling of P_n observations was used to determine the velocity structure of the uppermost mantle.

MODELING THE DATA

Based on the phase correlation described above, the first arrivals of the P_g phase were used to invert for the upper crustal velocity structure using a finite-difference tomographic method (Hole, 1992). The reflection phases P_1P , P_LP , P_2P and P_mP were used to determine the approximate velocity structure of the middle to lower crust with the X^2-T^2 method (Giese, Prodehl and Stein, 1976). After establishing an initial crustal P-wave velocity structure, the final P-wave model was determined using 2-D forward raytracing modeling (Cerveny, Molotkov, and Psencik, 1977; Cerveny and Psencik, 1984) and amplitude modeling using by the reflectivity method (Fuchs and Muller, 1971) and 2D ray methods. By adjusting the velocities and depths of the boundaries with raytracing method, the different phases on the record sections were all appropriately fitted for the traveltimes, and then the P-wave velocity model was established.

Because the intra-crustal boundaries were kept fixed, the S-wave velocity structure differs from P-wave velocity structure only in its velocity distribution. The upper crust shares similar characteristics to the P-wave structure, and just replacing P-wave velocity with S-wave velocity (assuming Poisson's ratio is 0.25) satisfies these data. The Two-dimensional forward modeling was used to fit the remaining S-wave phases. Finally, from the respective P- and S-wave velocity models, the distribution of Poisson's ratio can be calculated.

The accuracy of the final model is dependent on a large number of factors, such as shotpoint interval, receiver density, thickness of sediment in shallow and so on, but primarily the correct identification of the various phases and the number of ray paths intersecting a particular volume of the model. Perturbation of the models has shown that resolution of the velocity and depth to interface may be accepted as better than 2% and 5%, respectively, dependent on the uniformity of structure and the ray-path coverage.

Finally, the final P and S-wave crustal velocity structures of the profile along the Geoscience Transect from Taiwan to Altai, including the Poisson's ratio structure, are shown in Fig. 9. The models reveal obvious differences between tectonic units.

P and S Velocity Structure

The crustal velocity model (Fig. 9) shows many significant features. The velocity distribution near surface varies greatly laterally. In Altai block and the Junggar accretional belt, the velocity is very high ($V_p=5.5$ km/s, $V_s=3.1$ km/s). The Bogda shan and Tianshan accretional belt also share similar characteristics. In some Mesozoic and Cenozoic basins, however, such the Junggar, Tourpan-Hami and Dunhuang basins, the velocity is lower ($V_p=3.7\sim5.8$ km/s and $V_s=2.3\sim3.3$ km/s) than that around the basin, and increases rapidly with depth. In the Junggar Basin, the P-wave velocity near the surface is about 4.3 km/s ($V_s=2.5$ km/s) and increases to 5.8 km/s ($V_s=3.3$ km/s) at about 5 km below the surface. The Turpan-Hami Basin appears to have the thickest sediments, approximately 10 km, with the low velocity of 3.7 km/s ($V_s=2.3$ km/s) on the surface increasing to 5.9 km/s ($V_s=3.4$ km/s) above its basement. For the Dunhuang basin (eastern Tarim), the velocity

increases similarly from 4.2 km/s ($V_s=2.9$ km/s) to 5.8 km/s ($V_s=3.3$ km/s) over a depth of 6 km.

These data reliable outline the lateral and depth extent of sedimentary basins due to the clear contrast in velocity between basin fill and the top of the crystalline upper crust. Over most of the profile, the velocity of the crystalline upper crust is 6.0-6.1 km/s at depths between 8-14 km. However, beneath the Bogda shan, a higher velocity block ($V_p=6.30$ km/s, $V_s=3.7$ km/s) exists in the shallow crust.

The velocity in the middle crust is 6.6 km/s under the Altai block and Junggar accretional belt, and 6.5 km/s between Junggar and Turpan-Hami basins. Towards the southern part of the profile, a lower velocity layer, about 5 km thick and with a P-wave velocity of 5.9 km/s ($V_s=3.4$ km/s), is overlain by a higher velocity layer of 6.3 km/s ($V_s=3.6$ km/s). Because of the low velocity layer, the time delay of the reflections from Moho become obviously clear, as the phase P_mP shown on the record section of shot SP7 and SP10 in which the reflection traveltimes of P_mP (S_mS) phase in the south of Kushui (~750 km in the profile) is larger than in the north (see Fig.3, 6,7 and 8).

The thickness of the lower crust varies with tectonic province. especially in the thickness of the layer. The thickness averages 30 km with a velocity of 7.0 km/s ($V_s=3.9$ km/s) beneath Altai block and Junggar accretional belt, and the Moho is at a depth of about 54 km. The lower crust becomes thin obviously beneath the Junggar basin, where the depth of the Moho is close to 46 km. However towards south, the Moho becomes deeper in a form of two steps with a velocity of 6.9~7.0 km/s ($V_s\sim 4.0$ km/s), first step in Bogdashan and Turpan-Hami basin with a depth of 47 km and the second in the southernmost part with a depth of around 50 km.

The velocity distribution derived from P_n phases for the uppermost mantle varies from 7.7 to 8.0 km/s; the most significant characteristic is the lower value of 7.7-7.8 km/s under the region between Junggar and Turpan-Hami basin, however higher value of 8.0 /km appears beneath Altai block and Junggar accretional belt, Tianshan accretional belt and Tarim platform.

Poisson's ratio

The Poisson's ratio along the profile is shown in Fig. 9. For the sediments and weathering layer, Poisson's ratio is lower than 0.25, especially for the sediments in the basins. The Turpan-Hami Basin has a minimum value of 0.18~0.25, while the Junggar Basin has a higher value, 0.24-0.25, even when compared with other basins. However, in accretional belts, Poisson's ratio is higher, especially in Altai block and Junggar accretional belt with a value of 0.25, even in the Junggar basin.

In the upper crystalline and middle crust including lower velocity layer, the Poisson's ratio is around 0.25 except for Altai and Junggar region which is characterized by higher Poisson's ratio of 0.26~0.27.

The similar feature to middle crust appears in the lower crust with a value of 0.26~0.27 for the most of the profile, however, the value becomes higher beneath the Altai block up to 0.28.

According to the Poisson's ratio section, it seems to be obviously clear that, in a view of whole crust, Poisson's ratio is higher than other areas along the profile beneath the Altai block and Junggar accretional belt, especially the lower crust with the highest value of 0.28. In the adjacent area, under Junggar basin, Poisson's ratio above the lower crust is higher than any other region along the profile, its sediments also shares the same characteristics. In the Junggar basin, a high value of 0.26-0.27 predominates in the crust, the shallow part also shares the high value of 0.24~0.25.

DISCUSSION AND CONCLUSION

This profile resulted in a high quality data set which was used to derive the crustal structure (P and S-wave velocities and Poisson's ratio) beneath the area of the transect. These results reveal the characteristics of the crustal structure (Fig. 9) within the study area. The depth of Moho along the profile has a dramatic variation in the junction of the Junggar accretional belt and the Junggar basin from 54 to 46 km, however, in the south of the junction, the Moho of about 48 km with a slight variation has good agreement with the results inferred from teleseismic data (Feng et al., 1980; Lui et al., 1989; Teng et al., 1992 and 1994; Hanan Mahdi and Gary L. Pavlis, 1998).

The Poisson's ratio, an elastic deformation characteristic related to the composition and degree of disturbance of crystalline rocks, typically low for brittle and fractured rocks with high quartz content (Krillov et al., 1995b; Zandt et al., 1994; Zandt and Ammon, 1995; Zandt et al., 1995; Christensen, 1996; Rudnick and Fountain, 1995), becomes more and more important, and has the potential of providing valuable constraints on crustal composition and comprehensively understanding the nature of earth's crust. Now, as laboratory-based compressional and shear wave velocity measurements for common rock types become available, so the Poisson's ratios determined from field measurements are particularly important because the correlation between compressional wave velocity and composition is limited due to the similar compressional wave velocities of many common crustal rock types (e.g., Birch, 1960, 1961; Christensen and Mooney, 1995; Christensen, 1996). By combination of velocity structure with Poisson's ratio, an comprehensive interpretation of the crustal structure is possible (Fig. 10).

The crust in the north of the junction between Altai block and Junggar accretional belt is of highest Poisson's ratio of $\sigma=0.25-0.28$ and the greatest thickness with high velocities along the profile, probably implies that the crust enriches mafic composition and Precambrian basement probably exists there due to the high velocity both P and S-wave and high Poisson's ratio, which is related to the presence of gneissic rocks along the southern border (Chang, Ying, and Coleman, 1996). Comparing with some seismic results (Fig. 11) in the adjacent area (??????), especially from Russia, we find that, the crust in the northmost part, Altai block, has a very similar feature of velocity structure just with a variation of crustal thickness, this probably reflect the characteristics of the foreland of Siberian craton. However, there is a very distinct difference between Altai block and its south.

In the Junggar basin, there is much discussion concerning the basement, which may be composed of either Precambrian crystalline rocks or Paleozoic accretional rocks (Yang and Yang, 1985; Tao and Lu, 1980). The seismic cross section shows a higher Poisson's ratio of 0.26-0.27 than that of 0.25-0.26 in its northern side, especially in the upper and middle crust. This may imply a mafic-rich basement, probably Precambrian basement. With a consideration of the obvious variation in crustal thickness against both sides and other

geophysical evidences (L. Zhang, 1991) combined with the outcrops of Precambrian rocks around the Junggar Basin in the accretionary belts peripheral to the basin (C. Zhang, 1997), we prefer to infer the crust a Precambrian Massif or Precambrian crust other than oceanic crust imbricated with accretionary sediments.

The crust evolution of Bogdashaan and Turpan-Hami basin is relatively complicated, and there are some controversies about the nature of the crust. Along the wide-angle reflection/refraction profile, a lower Poisson's ratio of 0.25-0.26 in this region was observed. Lead systematics on the Tianshan post collisional granites south of the Nicolaev Line reveal isotopic ratios characteristic of Precambrian crustal rocks distinctly different than post collisional granites in the Junggaar accretional belt. The young age of the post-collisional thermal event has prevented fractionation and underplating typical for much older cratons (Rudnick and Fountain, 1995). The oldest exposed rocks in this region are Paleozoic ophiolitic, accretionary and arc rocks of oceanic affinity. The latest results from the isotopic variation of Nd, Sr, and Pb in Paleozoic granitoid Plutons along an east Junggar-Bogdashaan-Tianshan transect show that the distinctive differences exist between this region and the adjacent area, and that the primary magmas chiefly from depleted mantle sources were probably MORB-like basalt, extracted from upwelling asthenosphere behind downgoing subduction slabs and ponded at the base of the oceanic arc crust (Wen et al., 1998). According to Russian deep seismic sounding results (Krillov et al., 1995b), the low Poisson's ratio may imply that the block may consist of migmatized accretional crust produced by the thermal event related to the passive collision between the Junggar and Tianshan accretional belts and the crust has undergone homogenization and melting during the late Paleozoic thermal event marked by post collisional granites which are quartz-rich with much calc-alkaline intrusives. In other hand, because of the strong and frequent geological and tectonic activity, the crust become very fractured so that the Poisson's ratio within the crust becomes lower.

In the south of Turpan-Hami basin along the profile, Poisson's ratio for the basement and middle crust is also lower, probably due to the presence of granites formed in the same thermal event. The lower crust has a higher Poisson's ratio of 0.26-0.27 than above

due to fractionation of the older crust and perhaps development of granulite facies rocks in the lower crust. Because the fault Altyn Tagh is a strike-slip fault at the boundary between the Tarim Platform and the Kunlun-Qilian-Qinling fold system, the low velocity layer within the middle crust with a low Poisson's ratio of 0.25 can be considered to be composed of calc-alkaline intrusives in the middle crust near the fault zone. However, the Poisson's ratio becomes higher in the lower crust beneath the Dunhuang (Western Tarim) basin than that beneath Tianshan region, so it can be deduced that the crust, specially the lower crust, is not very mafic, in other words, the older crust in the southern part of profile may be Tarim Platform that was invaded by granitic materials formed during the thermal event that formed in the Late Palaeozoic collision and delamination and Kushui fault near shotpoint SP9 probably is the boundary between Paleozoic accretional belt and Tarim platform.

We have modeled the crustal velocity structure both P and S-wave and Poisson's ratio along the wide angle reflection profile in northwest China to investigate the crustal characteristics and possible crustal composition. In summary, we have inferred following conclusion according to the crustal model:

1. Beneath Altai and Junggar regions, a Precambrian basement probably exists by the evidence of high velocity both P and S-wave, high Poisson's ratio and some presences of Precambrian rocks within or around these regions.

2. A grand accretional belt maybe exists between the southern margin of Junggar basin and northern margin of Tarim platform and is composed of Bogda Shan, Turpan-Hami basin and Tianshan, being produced by the thermal event related to the passive collision between the Junggar and Tianshan accretional belts and the crust has undergone homogenization and melting during the late Paleozoic thermal event marked by post collisional granites which are quartz-rich with much calc-alkaline intrusives. The lower Poisson's ratio is mainly caused by the vast of post collisional quartz-riched granites. In other hand, the low Poisson's ratio also has the contribution of fractured crust which is characterized in this region.

3. The low velocity layer in the southern part of the profile probably is due to the calc-alkaline intrusives in the middle crust near the fault zone between Tianshan and Tarim.

ACKNOWLEDGEMENTS

We would like to express a special thanks for the support from the U.S. Geological Survey for the scientific exchange program. We thank those who provided advice on the data processing and interpretation during this research, including George A. Thompson from Stanford University, USA, C. Prodehl and F. Wenzel from the Geophysical Institute at Karlsruhe, Germany, G. Fuis, J.J.Luetgert and J. Hole from the U.S. Geological Survey, Takao Ohinato from the Japan Geological Survey, E.Gurria from Instituto Geografico Nacional, Spain. We also thank Dr. J. Hole for providing the data analysis code of the finite difference travel-time inversion and Takao for using his finite difference algorithm for 2-D heterogeneous media with transparent boundary conditions and nature topography to calculate the synthetic seismograms in this research. The Stanford China Industrial Group provided much new data concerning basin development and C.A. Hopson has shared new isotopic data on granites closely related to the transect.

ABSTRACT

During the seventh Five Year Plan of the People's Republic of China, the Ministry of Geology and Mineral Resources designed an ambitious geological and geophysical survey, the Geoscience Transect from Taiwan to Altay, as part of the International Lithosphere program in China. This project was carried out with integrated geological and geophysical methods. Among the geophysical methods, seismic refraction/wide-angle reflection techniques played an important role, and the 4300-km-long transect was covered by several end-to-end seismic profiles. The shotspacing along these profiles ranged from 28 km to 209 km, with an average shotspacing of 90 km. The charge size was 0.8-3.926 tons, depending upon the requirements of the area. Fifty-one shots were fired at 46 shot points. The spacing of stations was about 2 km near each shotpoint, 4 km for distances less than 300 km and 8 km beyond 300 km.

The major scientific goals of the project were: (1) to reveal the crustal and upper mantle structure and the tectonic features along the transect in detail, (2) to study the relationship between deep crustal and mantle structure, (3) to study the evolution of the Chinese landmass, and (4) to answer other fundamental geological questions.

1. INTRODUCTION

China's seventh Five Year Plan (1986-1990), a geological and geophysical project called the Geoscience Transect from Taiwan to Altay (GTTA), was carried out, which included several seismic refraction/wide angle reflection profiles (Fig.1). From the northwest towards the southeast of China, the transect crossed the Tianshan Fold System, the Tarim Platform, the eastern margin of the Tibetan Plateau, including the Qinling-Kunlun-Qilian Fold System and the Qinghai-Tibet Fold System, the Yangtze Platform and the southeast China Fold System (Shennan Yang and Weiran Yang, 1981). The geological and tectonic setting along the transect are complicated, and significant topographical relief defines the area.

The structure of the crust and the upper mantle along much of the transect has in the past only been studied with tomography using earthquake data (Rui Feng et al., 1980, Futian Liu et al., 1989, Jiwen Teng et al., 1992, Jiwen Teng et al., 1994). There are some controversial geological uncertainties along the transect, mainly concerning the geometry of the boundaries between different tectonic units at given depths. The purpose of the GTTA was to study the relationship between the crustal and upper mantle structure and the known tectonic features of China. The ultimate goal was to gain an understanding of the evolution of the Chinese landmass (Xuecheng Yuan, 1992, Youxue Wang, 1992, Xinzhong Xu and Youxue Wang, 1991). Because the transect is very long, 4,300 km, it was divided into five segments for simplification, by dealing with only a small portion at a time.

The project was coordinated by the Chinese Academy of Geoexploration, and involved numerous institutions and scientists, including the Chinese Academy of Geoexploration, the Chinese Academy of Geology, The Second Integrated Geophysical Brigade of the MGMR (the Ministry of Geology and Mineral Resources), Chengdu College of Geology, Changchun College of Geology, Xi'an College of Geology, and the Sichuan Seismological and Geological Brigade.

2. FIELD WORK AND DATA ACQUISITION

2.1 Environment

The local environment changes greatly from one end of the transect to the other. Line 1, for example, located in northwest China, crosses an arid landscape with a deep water table and high topographical relief. Lines 2 and 3 are located at the eastern margin of the Tibetan Plateau and contain extreme topographical relief; the maximum difference in elevation is more than 3000 meters. The conditions for transportation here are very poor, with some lakes and rivers near or across the profile lines. The water table is deep in most of the area throughout Lines 1, 2 and 3. For Lines 4 and 5, most of the area traversed is mountainous or hilly terrain with a shallow water table. In the northwestern areas, including Lines 1 and 2, the cultural noise is low due to low population density and few industries near the profiles. However, Line 3 has a high noise level due to a river which runs parallel to the profile. In the southeastern parts, the cultural noise is high as well.

2.2 Pre-site survey

The locations of the shotpoints and of all recording sites in the seismic survey were determined several months before the experimental expedition began. According to the designed profile, the sites were determined on a 1:50,000 topographical map with an accuracy of 25m. Each was marked with a colored tag in order to find it quickly and without complication during the experiment. The sites were generally located far from any source of cultural noise so the seismic signals would not be contaminated, and the shots were usually fired at midnight in order to avoid this contamination and to collect higher quality data.

2.3 Communication

Because the transect is very long, groups working on drilling, shooting and recording were not gathered in the same place, but were instead spread out along the profile according to the seismic experimental design. To ensure that the experiment would run smoothly, a communication system was required for the whole seismic refraction/wide angle reflection operation. For this purpose, a radio network was set up using a fixed frequency channel made available by the government. The system had several parts, a general station to issue, inform, or change the experiment plan, and several sub-stations for drilling, shooting and recording seismic data.

2.4 Drilling and shooting

A majority of the shots were fired in drill holes, but some were fired in lakes or rivers located along the profile. We learned that shooting in drill holes is more effective in producing seismic energy than is shooting in water, so we fired shots in drill holes as often as possible. Shooting in drill holes is more effective when the explosives in the drill hole are under or within the water table, so the holes were drilled deeper in areas where the environment was arid or the water table was deep. For large charges of up to 4 tons, a multi-hole array was required to hold the explosive and enhance the explosion energy. The explosive used in the seismic experiments was TNT.

Table 1 lists all shots fired along the transect during the experiments with their respective parameters.

Table 1. Shotpoint parameters in the experiments

2.5 Recording and Equipment

Analog seismographs were used during the experiments, two of which were 1-component and 3-component seismometers. Before 1988, both kinds of seismometers were used in the experiments, so Lines 3 and 5 have measurements of both types. One-component equipment was not used in the experiments after 1987.

Table 2. Equipment list used in the seismic experiments

Profile	Year	Number of Sensors		
		1-component	3-component	Total
Line 1	1988	0	168	168
Line 2	1989	0	168	168
Line 3	1987	60	168	228
Line 4	1986	0	60	60
Line 5	1986	70	130	130

For each profile, a consistency test for the seismometers was conducted at the beginning of the experiments. The time service system was the BPM time signal.

2.6 Design of the experimental layout

The layout for the seismic survey was designed in accordance with the main goals and environmental conditions prior to experimentation. Usually, reversed observation systems were used in the experiments. The receiver stations were tightly spaced near the shotpoints to study the detailed structure of the shallow crust. The spacing was increased at large distances from the receivers to record the Pn phase from the uppermost mantle.

In order to study the velocity structure of the crust and the uppermost mantle in detail, the shotpoints were spaced as close together as possible. On Line 1, and for the profiles in southeastern China, the shotpoint spacing was generally less than 100 km. On the Qinghai-Tibet Plateau, because of the poor transportation and drilling conditions, the shotpoint spacing was very large. The greatest shotpoint spacing in this area was more than 200 km (Fig. 2).

3. DATA EVALUATION

With 51 shots, 48 record sections were obtained during the seismic experiments. Most of these sections display high quality P-wave and S-wave data from 3-component seismometers (Fig.3). In some cases, shear wave data was also acquired with the 1-component seismometers (Fig.4).

In the seismic wave field, the Pg, Sg, PmP and SmS phases have a strong amplitude and are easily identified. The refraction phase from the uppermost mantle, Pn, can be identified because it is the first arrival at distances greater than 200 km in some sections along the transect. The Sn phase is more difficult to identify, as it is a secondary wave.

From the 3-component record sections, it can be found that shear wave phases are easier to identify in the horizontal components (L- and T- components) than in the vertical component (Z-component).

4. DATA PROCESSING AND INTERPRETATION

The data from the seismic profiles along the Geoscience Transect were recorded on analog tapes. The analog seismic records (100 samples/s with a 60 second sampling length each) were digitized by A/D transformation on an IBM-compatible PC/386, so that the data included both P- and S-wave information. Digital processing of the data included clock drift corrections and frequency filtering before plotting the data in the form of reduced time-distance record sections. The record sections were plotted with a reduction velocity of 6.00 km/s for P-waves and 3.46 km/s for S-waves. In order to perform phase identification and correlation, the time scale for S-waves used in plotting the record section is equal to that of the P-wave divided by 1.73 (J.P. Castagna, 1985, W.S. Holbrook et al., 1988, R.A. Eesley, 1989).

Following the phase correlation and identification, an initial interpretation was made. First, a 1-D crustal and upper mantle velocity model was obtained by 1-D inversion methods (K. Fuchs and G. Muller, 1971). Then a 2-D crustal and upper mantle model was established with 2-D ray-tracing methods (P.Giese et al., 1976, V.Cerveny et al., 1977). The P-wave velocity structure for the crust and upper mantle along the GTTA is shown in Fig.5.

5. CONCLUSION

The seismic experiment along the Geoscience Transect from Taiwan to Altay is the longest transect in the world. It was a great success which provided excellent data for the in depth study of the structure of the crust and upper mantle under China.

From these seismic experiments, much information was gained about field work, data processing and interpretation and the crustal and upper mantle structure along the profile. Many detailed studies were completed using information gained from the field work. The P-wave velocity structure of the crust and upper

mantle was also established for the Geoscience Transect, and will be published soon. During the experiments, high quality P- and S-wave data were acquired. It is this combination of P- and S-wave data which makes it possible to study the crustal and upper mantle structure in detail, especially in regards to the composition of these units (D. Gajewski et al., 1990, W.S. Holbrook et al., 1992). The study of the S-wave velocity structure will be continued further.

ACKNOWLEDGEMENTS

We would like to thank all those who took part in the seismic experiments along the Geoscience Transect from Taiwan to Altay. During its execution, some scientists, such as George A. Thompson from Stanford University, USA, C. Prodehl and F. Wenzel from Geophysical Institute at Karlsruhe, Germany, provided advice on the data processing and interpretation. Also some academic exchanges were held with the Geophysical Institute at Karlsruhe and the US Geological Survey.

Abstract. We present a new crustal cross section through the east-west trending ultrahigh-pressure (UHP) Dabie Shan orogenic belt, east central China, based on a 400-km-long seismic refraction profile. Data from our profile reveal that the orogenic blocks north and south of the orogen are composed of 35-km-thick crust consisting of three layers (upper, middle, and lower crust) with average seismic velocities of 6.0 ± 0.2 km/s, 6.5 ± 0.1 km/s, and 6.8 ± 0.1 km/s. The crust reaches a maximum thickness of 41.5 km beneath the northern margin of the orogen, and thus the present-day root beneath the orogen is only 6.5 km thick. The upper mantle velocity is 8.0 ± 0.1 km/s. Modeling of shear wave data indicate that Poisson's ratio increases from 0.24 ± 0.02 in the upper crust to 0.27 ± 0.03 in the lower crust. This result is consistent with a dominantly felsic upper crustal composition and a mafic lower crustal composition within the amphibolite or granulite metamorphic facies. Our seismic model indicates that eclogite, which is abundant in surface exposures within the orogen, is not a volumetrically significant component in the middle or lower crust. Much of the Triassic structure associated with the formation of the UHP rocks of the Dabie Shan has been obscured by post-Triassic igneous activity, extension and large-offset strike-slip faulting. Nevertheless, we can identify a high-velocity (6.3 km/s) zone in the upper (<5 km depth) crustal core of the orogen which we interpret as a zone of ultrahigh-pressure rocks, a north dipping suture, and an apparent Moho offset that marks a likely active strike-slip fault.

1. Introduction

The Qinling-Dabie Shan orogenic belt was created by the Triassic subduction of the northern edge of the Yangtze craton and subsequent collision with the Sino-Korean craton (Figure 1). Widespread ultrahigh-pressure (UHP) coesite-bearing eclogite facies rocks in the eastern Dabie Shan indicate that during this collision, crustal rocks were subducted to depths >120 km and then exhumed [Hacker *et al.*, 1995a]. This Mesozoic orogen, however, is characterized by neither the prominent topography nor thick crust [Zeng *et al.*, 1995; Li and Mooney, 1998] that is expected in collisional orogens involving subduction of continental crust. To determine the deep crustal structure of the Dabie Shan, a 400-km-long deep seismic refraction profile was recorded in 1994. In this paper we present a two-dimensional (2-D) model of the crustal structure across the Dabie Shan and relate this structure to the processes that created and later modified the orogen. This model supersedes that of Dong *et al.* [1996], who presented a preliminary model based on only a portion of the seismic refraction available data.

2. Regional Geologic Setting

The Qinling-Dabie Shan orogenic belt extends WNW-ESE for more than 2000 km and contains abundant high-pressure metamorphic rocks including abundant coesite-bearing eclogite and blueschist facies rocks [Liou *et al.*, 1989]. UHP rocks crop out in the three easternmost ranges of the Qinling-Dabie orogen, in the Hong'an, Dabie, and Su-Jia areas (Figure 1). These rocks are believed to have been formed by north directed subduction of the Yangtze craton or of a microcontinent beneath the Sino-Korean craton. Structural [Hacker *et al.*, 1995a], metamorphic [Liou *et al.*, 1995], and geochronologic [Hacker and Wang, 1995; Hacker *et al.*, 1998] data from the Dabie Shan have been interpreted to indicate that exhumation of UHP rocks occurred in two stages. In the Triassic-Jurassic, large-scale normal faults brought the UHP rocks from eclogite facies to amphibolite facies depths [Hacker *et al.*, 1998]. From 133 to 122 Ma, northwest-southeast extension coincident with voluminous magmatism brought the UHP rocks to within 10–15 km of the surface [Hacker *et al.*, 1995a, 1998].

In the Dabie Shan area, there are three east-southeast trending belts separated by faults (Figure 2). (1) The Foziling Group consists of flysch that has been overlain by Cretaceous volcanic rocks. (2) The Dabie Shan contains a prograde high- to ultrahigh-pressure metamorphic sequence in its southern

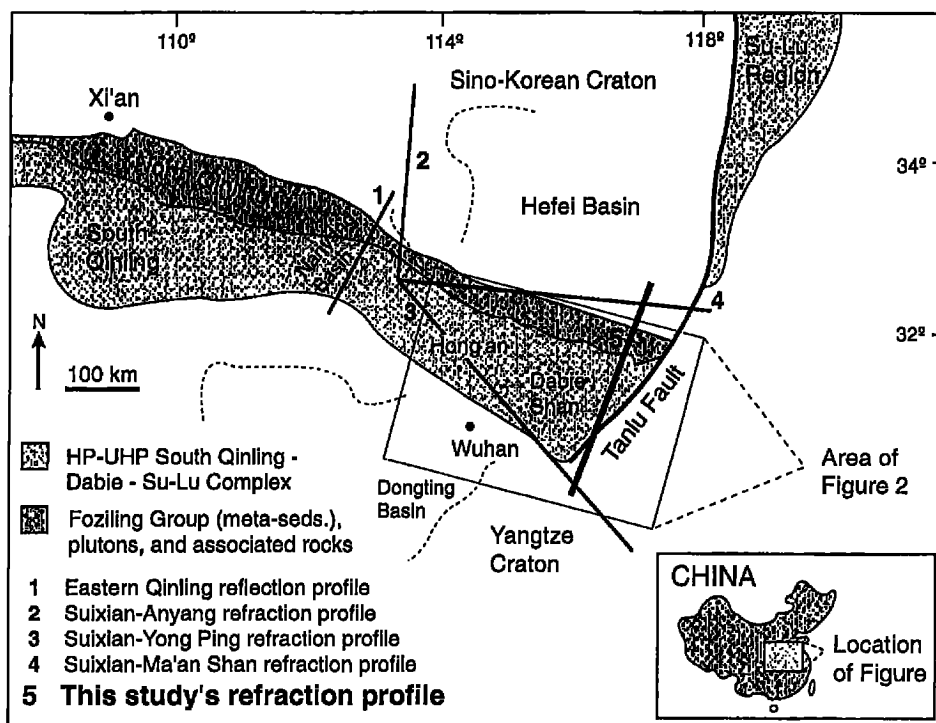

Figure 1. Geologic map of the Qinling-Dabie Shan orogenic belt in the central eastern China. The region is exceptional for the widespread occurrence of ultrahigh-pressure rocks, including coesite-bearing eclogite and rare diamonds. The Su-Lu region is displaced to the northeast of Dabie Shan by the Tan-Lu fault. Previously published seismic reflection and refraction profiles are indicated (citations in text).

half and Cretaceous plutons and orthogneiss in its northern half [Hacker *et al.*, 1995a]. (3) The Foreland fold belt comprises a thick series of late Proterozoic felsic volcanic rocks and fine-grained sedimentary rocks overlain by Late Proterozoic to Middle Triassic sandstone, limestone, and shale. South of the Foreland fold belt, there are east-west trending folds with several kilometer long wavelengths that continue across the southward projection of the Tan-Lu fault.

The Dabie Shan complex and the Foziling Group are abruptly truncated to the east by the Tan-Lu fault (Figures 1 and 2). This apparently sinistral fault may have formed in the Triassic during the continental collision between the Sino-Korean and Yangtze cratons [e.g., Yin and Nie, 1993], and dextral displacement is thought to have continued through the Jurassic and Early Cretaceous [Xu *et al.*, 1987; Chen *et al.*, 1988]. Today this fault is expressed as a post-Late Cretaceous normal fault between the Dabie Shan complex and the Foreland fold belt.

3. Previous Geophysical Results

Although this study is the first seismic profile across the Dabie Shan itself, there are several nearby seismic reflection and refraction profiles (Figure 1). The Eastern Qinling reflection profile [Yuan *et al.*, 1994] is ~300 km west of the Dabie Shan. This profile images the Qinling orogen that separates the Sino-Korean and Yangtze cratons. According to Yuan *et al.* [1994] the reflection data provide evidence that late in the collision process the lower crust of the Qinling orogen was

subducted southward beneath the Yangtze craton, whereas the upper crust, was overthrust on a large scale to the south.

Three seismic refraction profiles are located west, south, and north of the orogen (Figure 1). These are the Suixian-Anyang profile [Hu *et al.*, 1986], the Suixian-Yongping profile [Group of Industrial Explosion Observation, 1988] for which a geoscience transect was compiled [Wang *et al.*, 1995], and the Suixian-Ma'an Shan profile [Zheng and Teng, 1989]. All three profiles recorded industrial explosions near the city of Suixian. South of the Dabie Shan, the crustal thickness is 34 km, and the average crustal velocity is 6.35 km/s [Group of Industrial Explosion Observation, 1988]. North of the Dabie Shan, the Hefei basin has a 32-km-thick crust with an average velocity of 6.25 km/s [Zheng and Teng, 1989]. The Suixian-Anyang profile passes through the southern portion of the Sino-Korean cra-

Table 1. Locations of Shot Points

Shot Point	Name	Latitude N	Longitude E
ZhM	Zhuangmu	32°23.6'	117°07.7'
GuT	Guantun	31°50.1'	116°52.3'
BuT	Butasi	31°28.9'	116°44.5'

CaS	Caishan	29°51.6'	115°48.9'
ZhG	Zhuanggongdu	29°09.1'	115°39.1'

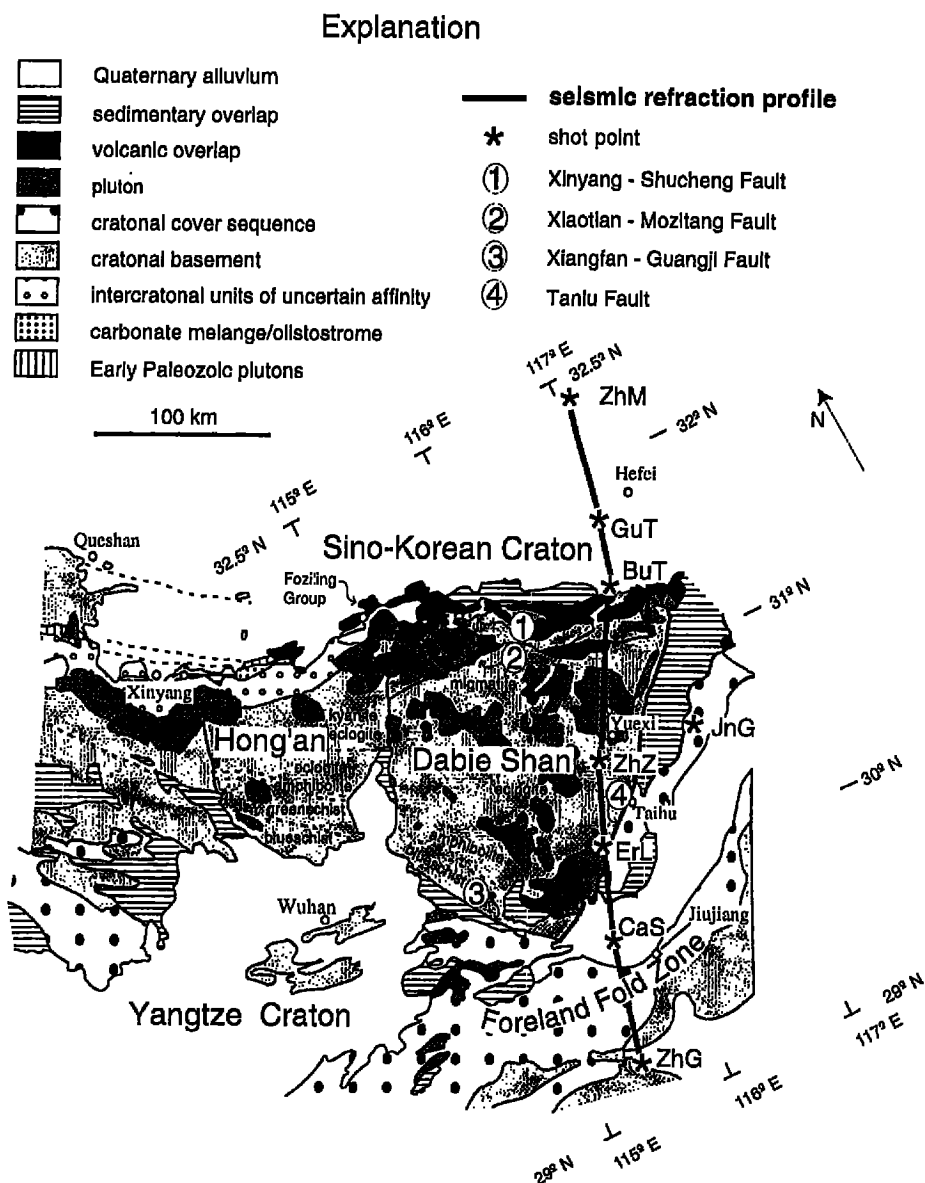

Figure 2. Geologic setting of the Dabie Shan and location of the seismic refraction profile [after Hacker *et al.*, 1995b]. Shot points are ZhM (Zhuangmu), GuT (Guantian), BuT (Butasi), ZhZ (Zhuangzhong), JnG (Jingong), ErL (Erlanghe), CaS (Caishan), and ZhG (Zhanggongdu).

ton, which has a 34-km-thick crust with an average velocity of 6.30 km/s [Hu *et al.*, 1986].

The Bouguer gravity data in the study area delineate an ellipsoidal negative anomaly with a -50 mGal average and -75 mGal low centered on the Dabie Shan (i.e., 50 km west of shot point ZhZ, Figure 1) [Qiu and Guo, 1989]. The negative anomaly correlates with higher topography (~ 1200 m) and a small (6.5 km) crustal root, as described below. The gravity data have not been modeled in this study.

4. Layout of the Profile

Our seismic refraction profile trends N25°E and begins in the north within the Hefei basin of the Sino-Korean craton,

passes through the Dabie Shan, and ends in the Yangtze craton. The profile crosses four significant strike-slip faults from north to south: the Xinyang-Shucheng, Xiaotian-Mozitang, Xiangfan-Guangji, and Tan-Lu faults (Figure 2).

Eight shots (Table 1) were recorded by a total of 150 analog recorders. Seismic energy was generated by borehole explosions, with the exception of the shot at ZhZ (Figure 2), which was an underwater explosion. Shotpoints were spaced ~ 50 km apart, with the exception of shot points BuT and ZhZ which were ~ 90 km apart. The explosive charge of each shot varied from 1000 to 2000 kg, based on the site conditions and the maximum shot-recorder distance. Seismic recorders were spaced 3–4 km outside the orogen and were 1 km apart within the orogen to obtain higher resolution. Most recorders were

three-component seismographs with 1-Hz geophones. The analog records were digitized with a 10-ms sampling interval.

5. Data Interpretation

5.1. General Analysis of Seismic Phases

A complete set of all record sections are presented here. Details of the individual sections will be discussed below. Methods of interpretation of seismic refraction data and model uncertainties are discussed by Mooney [1989], who estimates that seismic velocities are accurate to better than 3% and boundary depths (e.g., Moho) are accurate to better than 10% of the calculated depth. The phases P_g and P_n are recognizable as the first arrivals on all record sections. P_g , the refracted wave propagating within the upper crust, is observed at distances of <100 km. P_n , the refraction within the uppermost mantle, is a first arrival at distances beyond 160 km.

Besides the P_g and P_n phases, four other phases can be recognized as secondary arrivals with highly variable clarity. The most prominent secondary phase, PmP , is a wide-angle reflection from the crust-mantle boundary. This phase is visible for all shots. Additional wide-angle reflections, labeled P_1 , P_2 , and P_3 , are variably observed from intracrustal interfaces. These reflections are generally weaker than PmP . One reason for this may be seismic scattering caused by fine-scale structure [Levander et al., 1994]. While it is generally accepted that the crust is grossly layered and that velocity generally increases with depth [Meissner, 1986; Mooney and Brocher, 1987; Christensen and Mooney, 1995], fine-scale structure can also effect the seismic response of the crust. Numerical modeling demonstrated that such fine-scale structure can be misinterpreted to indicate crustal layering [Mereu and Ojo, 1981; Ojo and Mereu, 1986; Levander and Holliger, 1992; Levander et al., 1994]. Our interpretation is based on the assumption that the phases P_1 , P_2 , and P_3 are ray geometric (i.e., specular) reflections. However, we acknowledge that fine-scale structure probably is also significant. It is unlikely, based on the evidence from global seismic reflection profiles, that the crust contains continuous, smooth specular reflectors at the scale of this study [Levander and Holliger, 1992]. Thus our model is an internally consistent (i.e., satisfying observations from multiple sources and receivers), layered approximation to a heterogeneous crust. Only significantly more dense seismic data will reveal how close this model is to the fine-scale structure.

5.2. Shot Point ZhM (Zhuangmu)

Shot point ZhM (Figure 3) is located in the Hefei basin of the Sino-Korean craton. P_g has an apparent velocity of 6.15–6.25 km/s at distances from 40 to 75 km. P_1 is a reflection with an apparent velocity of 6.2 km/s between 55 and 90 km. Reflection P_2 is observed between 100 and 140 km with an apparent velocity of 6.2–6.3 km/s. However, the precritical reflection for the phase P_2 is not clear at distances of <100 km, perhaps due to crustal scattering, as mentioned above. PmP is a very clear, high-amplitude phase from 70 to 270 km. The PmP waveform near the critical angle is remarkably simple, with an abrupt onset that we have modeled using synthetic seismograms with a first-order transition and a significant (~1.0 km/s) jump in velocity. Such crisp PmP waveforms are common in regions that have experienced crustal extension, such as much of western Europe and the Basin and Range [Cutchings and Mooney, 1991; Jarchow et al., 1993]. The average crustal velocity, calculated from PmP travel times between

70 and 200 km on the section ZhM, is 6.25 km/s. A strong secondary phase with a low apparent velocity of ~6.1 km/s that appears to be a continuation of PmP is observed from 200 to 270 km following P_n . This phase (P_x) cannot simply be the asymptotic wide-angle PmP reflection because, in this case, the apparent velocity would be equal to the velocity of the lower crust (6.6–6.9 km/s in this region). The travel time and amplitude of this phase are similar to a prominent phase observed on the Suixian-Ma'an Shan profile [Zheng and Teng, 1989] are several possible interpretations of it. Zheng and Teng [1989] considered it to be a diffracted wave from the Moho. However, we are able to obtain an excellent travel time fit to the phase P_x with a reflection from the bottom of a modest low-velocity zone at a depth of 17 km. This interpretation is essentially the same as that of Ye et al. [1995], who observed a similar prominent phase in data from the Swiss Alps. P_n is a clear first arrival beyond the distance of 160 km and has an apparent velocity of about 8.0 km/s.

5.3. Shot Point GuT (Guantian)

Shotpoint GuT (Figure 3) is also in the Hefei basin, ~66 km south of shot point ZhM. In record section GuT-north the apparent velocity of P_g is about 6.15 km/s, in agreement with the reversing data from shot point ZhM. On section GuT-south the apparent velocity of the P_g phase is 6.2 km/s. Phase P_1 has an apparent velocity of 6.25 km/s between 70 and 110 km. P_2 is a clear reflection at distance between 120 and 160 km, but is very weak at pre-critical distances. PmP is the highest amplitude arrival at distance between 80 and 140 km, but it is not clear beyond 140 km. P_n , with an apparent velocity of 8.1 km/s, is observed as a clear first arrival beyond 170 km.

5.4. Shot Point BuT (Butasi)

Shot point BuT (Figure 4) is located in the Foziling schist, ~10 km north of the active strike-slip Xinyang-Shucheng fault, and ~40 km north of the Cretaceous left-lateral, normal Xiaotian-Mozitang fault. On section BuT-north the apparent velocity of P_g is 6.0 km/s, 0.2 km/s less than the reversed observation (section GuT-south). A deepening of the basement to the north is likely to cause this difference. The phase P_1 can be traced between 30 and 70 km. The phases P_2 and P_3 cannot be recognized on the north section due to the sparse station spacing. PmP is clearly observed at distances of 70–110 km.

On record section BuT-south, P_g arrival times are about 0.5 s earlier than on the section to the north. This confirms a northward dipping basement. In addition to P_1 , there are two intracrustal reflection phases (P_2 and P_3) that are variably visible on the section. Phase PmP is once again very clear and is dominant at distances between 90 and 160 km. PmP travel times at distances of 90–140 km on record section BuT-south are ~1.0 s later than the travel time on section BuT-north. This indicates that the Moho deepens to the south of BuT. The PmP travel times for BuT-south are also about 1.0 s later than for GuT-south (Figure 3), also indicating that the Moho deepens south of shot point BuT.

5.5. Shot Point ZhZ (Zhuangzhong)

Shot point ZhZ (Figure 4) is located within the coesite-bearing eclogite unit, with the receivers to the south passing through the UHP zone. The Cretaceous synmagmatic normal fault that dropped the coesite-eclogite unit down relative to the northern orthogneiss in the footwall is exposed a few kilometers north of the shot point. Unlike the other shots, the expo-

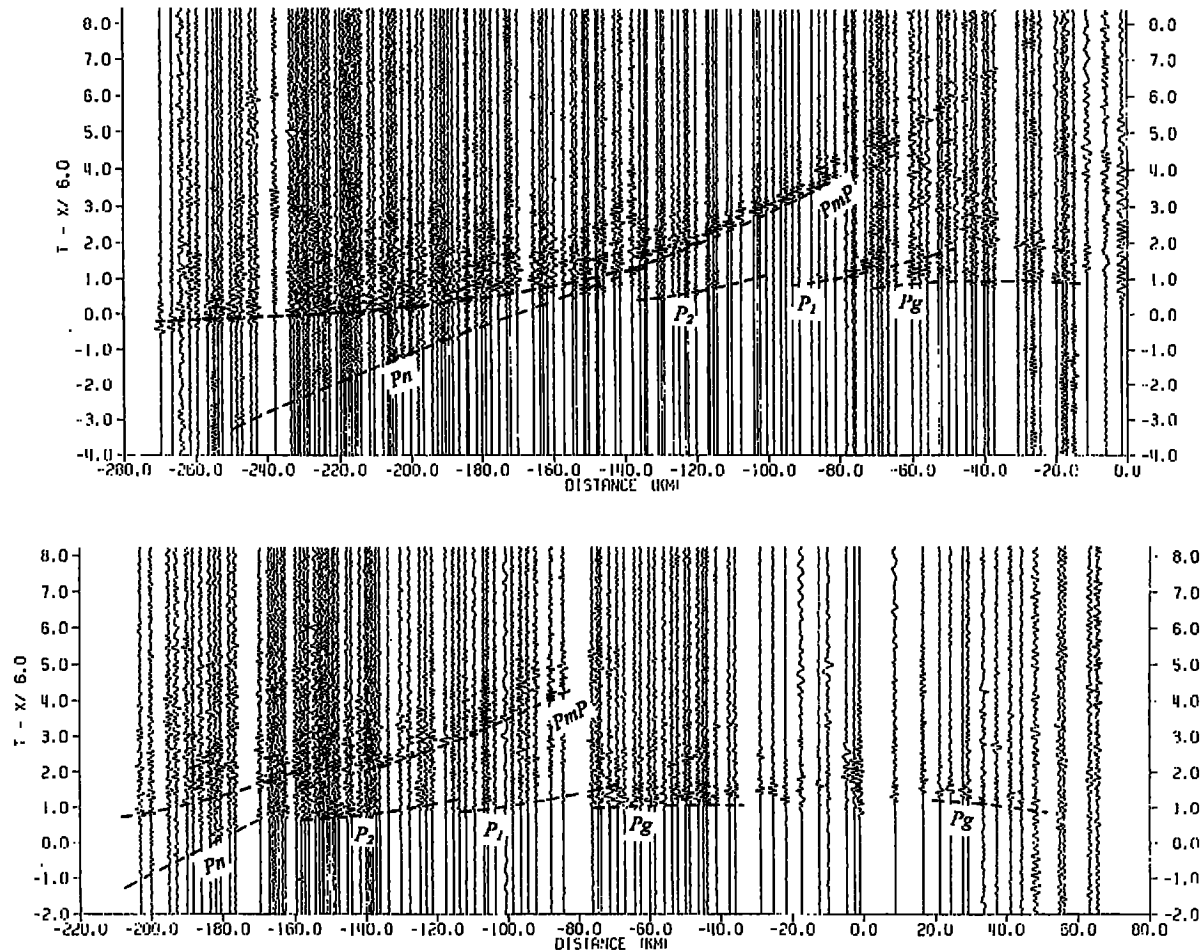

Figure 3. (top) Trace-normalized low-pass filter (10 Hz) record section of shot point ZhM. For this and all other record section the travel time curves are theoretical curves calculated from the final velocity model. Shot point locations are shown in Figure 2. The dominant phases on the section are (1) *PmP* (reflection from Moho), which has a very simple waveform near the critical distance (~120 km), and (2) *P₂*, which has a low (6.1 km/s) apparent velocity and is interpreted as a wide-angle reflection from the bottom of midcrustal low-velocity zone (see text for additional discussion). The phase refracted just below the Moho (*P_n*) is clearly recorded as a first arrival. The corresponding shear wave phase *S_n* was not observed. (bottom) Record section of shot point GuT. The dominant phase *PmP* stops at about 145 km. The intracrustal phases *P₁* and *P₂* are weakly recorded at precritical distances (less than ~80 km), possibly due to scattering in the crust.

sion was detonated under water, and reverberations with higher-frequency content are observed on the records.

On record section ZhZ-north, *Pg* has an apparent velocity of 6.0 km/s. The upper crustal reflection *P₁* is weaker than that in the section to the south. Phase *P₂* can be traced from 50 to 120 km. *P₃* is not at all clear. *PmP* is the strongest phase on the section beyond 80 km.

On record section ZhZ-south, *Pg* has an apparent velocity of 5.95 km/s. A distinct phase *P₁* with larger amplitude than that of the *Pg* phase can be traced from 20 to 70 km. This phase is also strong on the section JnG-south (see below). The phases *P₂* and *P₃* are not clearly observed. The shot point-recorder distances are too short to record either *PmP* or *P_n*.

5.6. Shot Point JnG (Jingong)

Shot point JnG (Figure 5) is located on the Yangtze craton, east of the Tan-Lu fault. It is offset ~50 km east of the main

line. Because the main line is not perfectly straight, the records beyond 70 km can be approximated as in-line observations (Figure 2). The travel time of the phase *PmP* for propagation to the north is similar to ZhZ-north. The phase *PmP* is also clearly observed on section JnG-south, and this observation is important in view of the lack of *PmP* from section ZhZ-south.

5.7. Shot Point ErL (Erlanghe)

Shot point ErL (Figure 5) is located in the southern half of the high-pressure metamorphic belt, just west of the Tan-Lu fault. The apparent velocity of *Pg* is 5.95 km/s, in agreement with section ZhZ-south. Although the phase *P₁* behind *Pg* can be traced to 120 km, its energy is weaker than the *P₁* on section ZhZ-south. Similar to section BuT-south, phase *P₂* is strongest at distances of 120–150 km. *PmP* is dominant beyond 80 km and consists of a simple waveform with an abrupt onset. The arrival time at 100 km is 0.5 s earlier than on sections ZhZ-

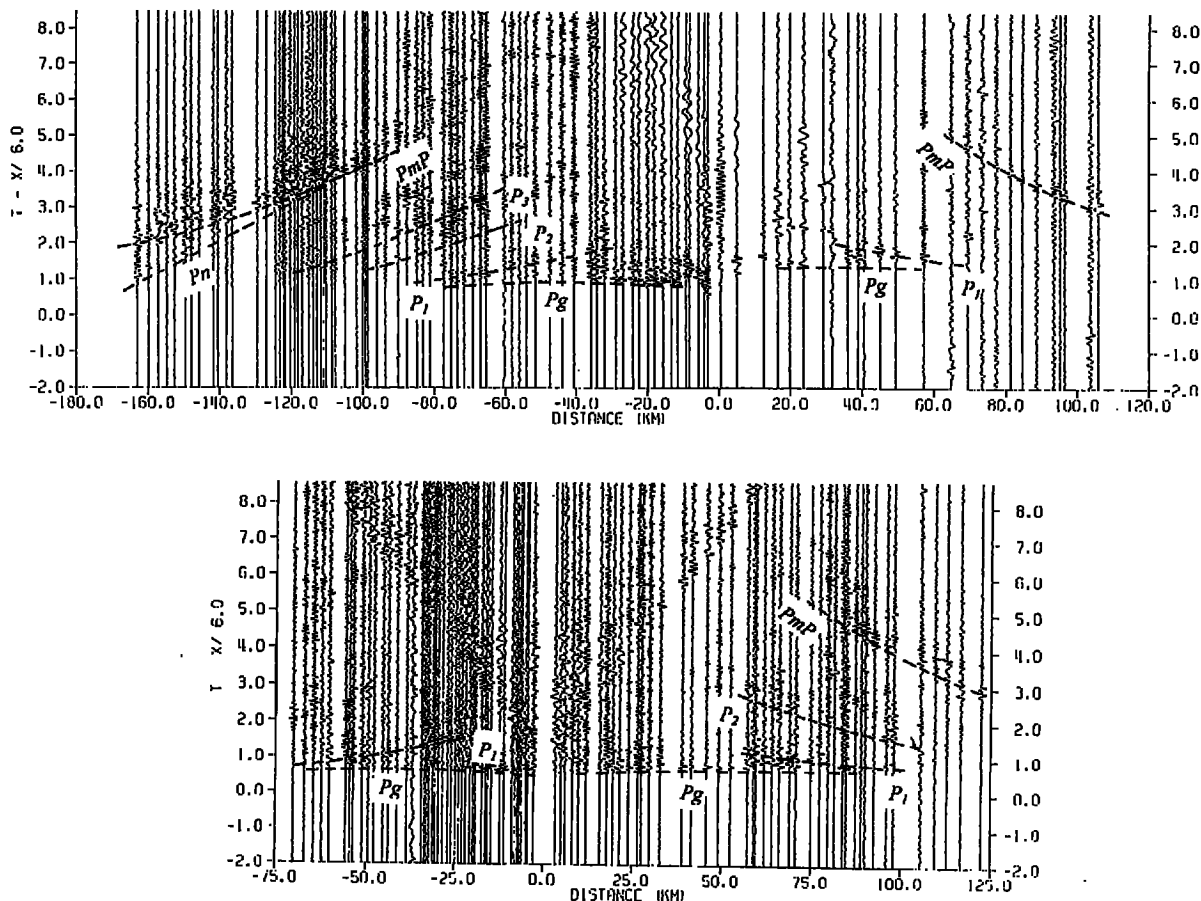

Figure 4. (top) Trace-normalized low-pass filter (10 Hz) record section of shot point BuT. The Moho reflection, PmP , is a strong phase in the data recorded to the south. Two intracrustal reflection phases, P_2 and P_3 , are evident with variable amplitude before the phase PmP . Station spacing averaged 4 km to the north of the shot point. (bottom) Record section of shot point ZhZ. A distinct reflection phase (P_1) is evident 0.3 to 0.7 s behind the Pg phase on the record section to the south. The Moho reflection, PmP , is clearly recorded to the north, and there is abundant seismic energy following the first arrival, Pg , and before PmP . We identify three intracrustal reflected phases, P_1 , P_2 , and P_3 , but scattering may also contribute to this seismic energy.

north and BuT-south. Pn is weaker than on sections of ZhM and GuT-south. Except for Pg and PmP , all of the phases on the section are weaker than on the section BuT-south.

5.8. Shot Point CaS (Caishan)

Shot point CaS (Figure 6) is located in the fold-thrust belt south of the Dabie Shan, close to the Yangtze River. On section CaS-north, Pg is generally obscured near the shot point due to the high background noise. P_1 and P_2 are observed variably. The arrival time of PmP is basically the same as that of ErL-north. The profile is not long enough for Pn to be recognized as the first arrival. Although there is only a short observation distance (~ 10 km) south of the shot point, we can easily see from the late Pg arrival time that the basement deepens beneath the Yangtze River valley.

5.9. Shot Point ZhG (Zhanggongdu)

Shot point ZhG (Figure 6) is located in the Yangtze craton. Pg can be traced from 10 to 60 km with an apparent velocity of 5.9 km/s. Between Pg and PmP , intracrustal reflection P_2 is

evident from 70 to 110 km. The PmP travel time at a distance of 100 km is similar to that on sections CaS and ZhM. Pn appears beyond ~ 160 km as the first arrival and has an apparent velocity of ~ 7.9 km/s.

6. Two-Dimensional Modeling

A finite difference tomographic inversion method [Vidale, 1988, 1990] was used to model the upper crustal velocity structure based on the Pg arrivals. Modeling of the middle and lower crust and uppermost mantle was then carried out using 2-D forward ray tracing. The travel times and amplitudes of all of these seismic phases have been calculated using the programs "MacRay" [Luetgert, 1992] and "SEIS-83" [Cerveny *et al.*, 1977; Cerveny and Psencik, 1984]. Synthetic seismograms have been calculated using the asymptotic ray theory [Cerveny and Psencik, 1984].

In the finite difference travel time method, travel times are extrapolated outward from the source region to each point in the model [Vidale, 1988, 1990]. We used an inversion method

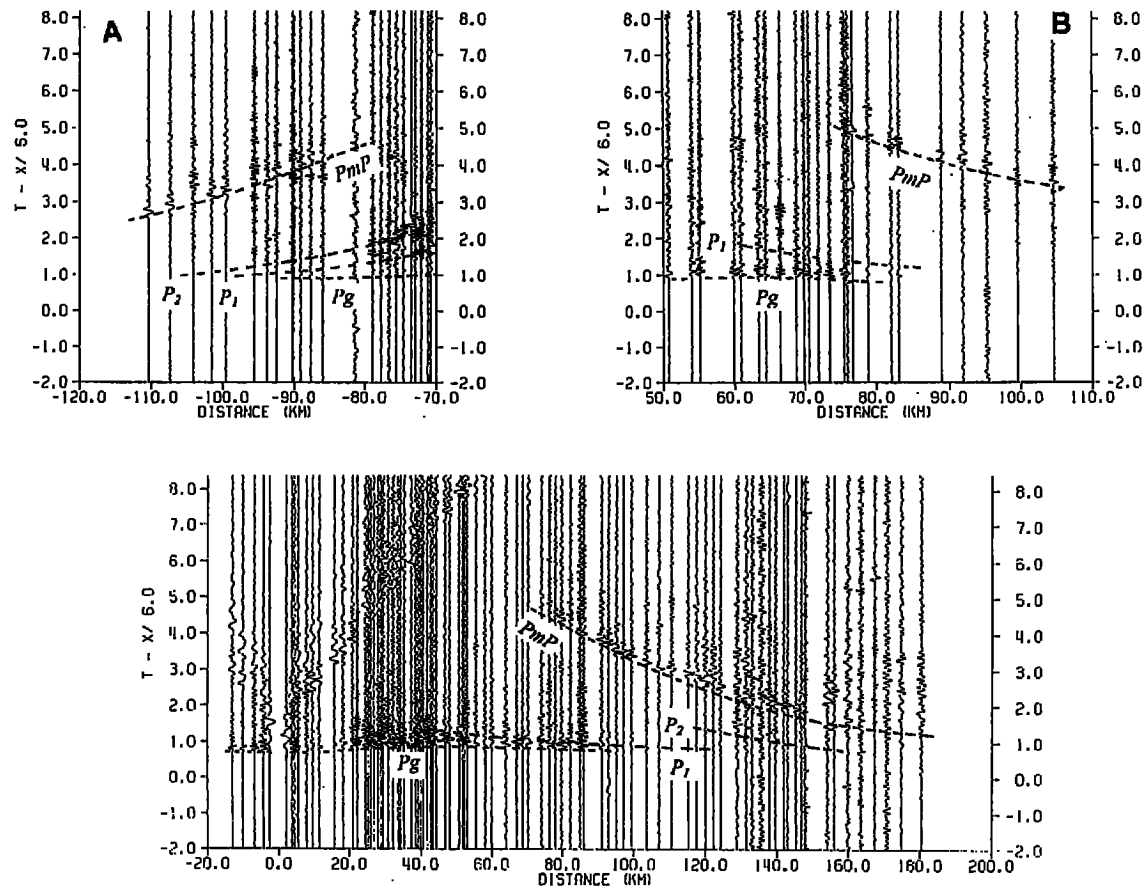

Figure 5. (top) Trace-normalized low-pass filter (10 Hz) record section of shot point JnG, which was located off-line. The reflection from Moho, PmP , is clearly recorded and is delayed on the section to the north relative to the section to the south. Intracrustal reflections, labeled P_1 and P_2 , are clear only on the data to south where the station spacing is 1–2 km (70–80 km distance range). (bottom) Record section of shot point ErL. The PmP reflection is very clear, and the travel time curvature constrains the average crustal velocity to ~ 6.3 km/s. The intracrustal reflection P_2 is well recorded at distances around 140 km. The refraction from to uppermost mantle, Pn , is not visible in these data.

capable of imaging media containing strong velocity variations [Ammon and Vidale, 1993; Hole, 1992]. The inversion model was parameterized using 4-km cells. To maintain accuracy, a uniform 1 km square grid was used for the travel time calculation. A total of 479 Pg arrival times were used in the inversion. The final velocity model (Figure 7a) was obtained after 5 iterations. The RMS travel time residual decreased from 0.35 to 0.10 s for the model. There is no significant difference between the models obtained after 5 and 10 iterations. The resolution of the inversion was assessed by summing the number of rays traveling through each cell (Figure 7b). The central part of the profile (between 90 and 270 km) was covered by more than 25 rays. The rays in the area between 100 and 200 km on Figure 7b do not penetrate below a depth of ~ 5 km due to the presence of a high-velocity zone. Velocities at depths < 5 km are well resolved, especially in the central part of the profile. The most prominent feature is a high-velocity (6.3 km/s) zone beneath shotpoint ZhZ, in the middle of the UHP zone. We discuss this feature below.

The crustal structure below ~ 10 km was determined from the wide-angle reflections. As discussed earlier, phase P_1 has a

high amplitude on the record section of ZhZ-south. The difference of travel time between P_1 and Pg at distances of 20 and 70 km are 0.75 and 0.3 s, respectively. The calculation of synthetic seismograms indicates that a higher velocity layer (6.4 km/s) beneath an interface at a depth of ~ 7 km provides a good match to the Pg/P_1 amplitude ratio. The high-velocity (6.4 km/s) layer is modeled as a thin layer in order to fit the travel times of later arriving phase, (i.e., P_2 , P_3 , PmP) and because a thicker layer at shallow depth would cause an unreasonably large gravity anomaly.

Figure 8 shows the comparison between observed and calculated travel time data and between observed and synthetic seismograms from shot point BuT. The observed and calculated travel times and amplitudes are in reasonable agreement. The greater complexity of the observed wave field compared with the synthetic wave field indicates that the crust does not contain continuous, smooth specular reflectors, as was mentioned earlier. Scattering in the crust may also contribute to the amplitude misfits between the calculated and observed intracrustal phases.

The 2-D crustal velocity structure across the Dabie Shan is shown in Figure 9a. The contoured velocity values are the

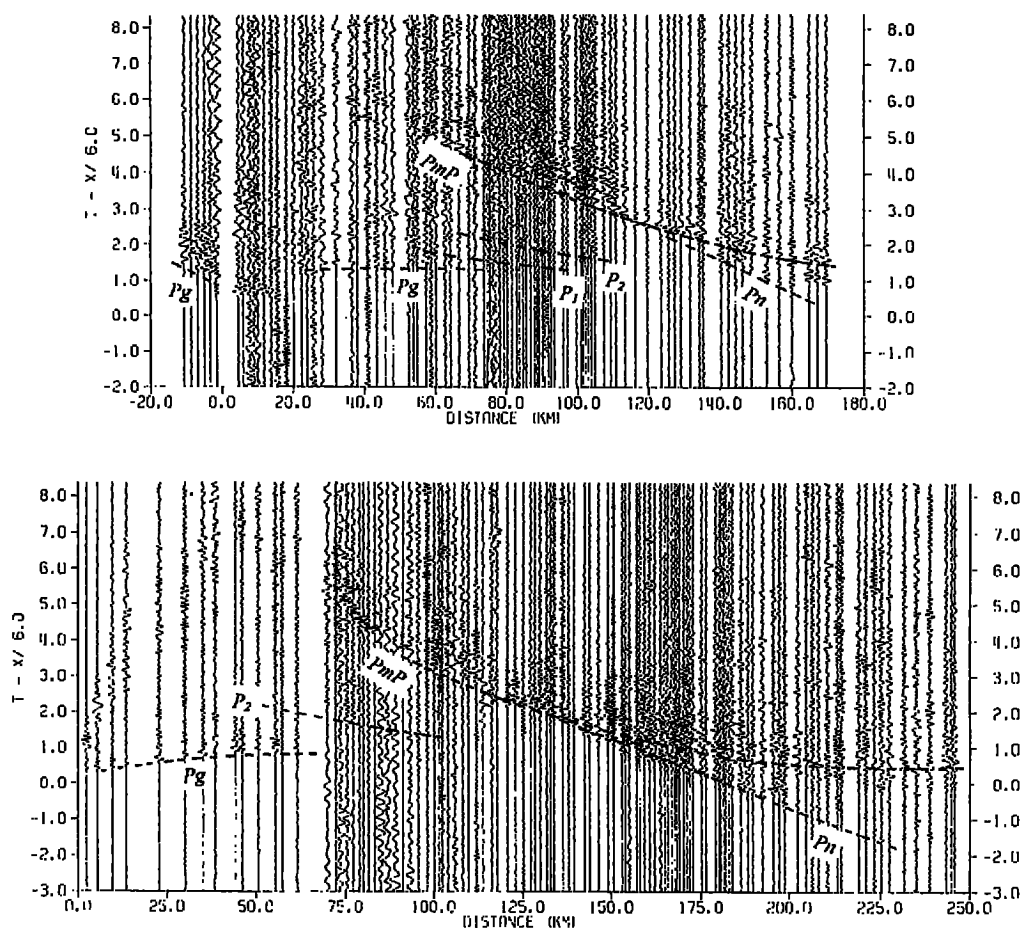

Figure 6. (top) Trace-normalized low-pass filter (10 Hz) record section of shot point CaS. *PmP* is clearly observed, but the intracrustal reflections *P₁* and *P₂* are not highly coherent phases, even in the most densely recorded portions of the profile. Seismic scattering may play a role in the generation of the *P₁* and *P₂* phases. (bottom) Record section of shot point ZhG. *PmP* and *Pn* arrival phases are clearly observed. These observations, together with the reversing profile from shotpoint ZhM-south, and provide strong constraints on the average crustal velocity, crustal thickness and uppermost mantle velocity.

result of iterative forward modeling of seismic travel times of phases arriving after *Pg*. The location of seismic control on the depth of the crustal boundaries is indicated by heavy solid lines. The Moho discontinuity is ~6 km deeper beneath the Xiaotian fault than beneath the Sino-Korean and Yangtze cratons, where an offset of ~3.5 km appears to exist. The Moho offset was inferred from (1) a travel time difference of 1.0 s for the *PmP* reflection as recorded from shot points GuT and BuT, even though the distance between the two shot points is only 40 km (Figures 3 and 4); (2) *PmP* arrivals from shot point GuT-south, which are very clear from 90 to 145 km and are abruptly interrupted at the distance of ~145 km (Figure 3); and (3) the clear travel time difference of 1.0 s for *PmP* from BuT-north versus BuT-south (Figure 4).

7. S Wave Velocity and Poisson's Ratio

The horizontal components of the seismic records were used to determine the shear wave velocity structure beneath the Dabie Shan. The phases *Sg* and *SmS* appear clearly on the record sections of most shot points (e.g., ErL in Figure 10).

However, the uppermost mantle phase *Sn* can not be identified on the record sections. In addition, the converted wave *PmS* reflected from the Moho can be recognized on the records of BuT and JnG. The *S* wave velocity model was obtained using two-dimensional ray tracing, as for the *P* wave model. *S* wave velocities and Poisson's ratio within the crust are shown in Figure 9b. Fourteen out of fifteen values of Poisson's ratio are in the range 0.23–0.27 (one value is 0.29). Because the *S* wave phases reflected on the intracrustal interfaces are generally more difficult to identify than *P* wave reflections, the *S* wave velocities in the midcrust have larger uncertainties. However, the very clear *PmP* and *SmS* reflections provide very good constraints on the average whole crustal Poisson's ratio (0.25–0.26; Figure 9b). The fact that the many record sections contain both clear *Pn* and *SmS* phases, but lack the phase *Sn*, may indicate a negative *S* wave velocity gradient in the uppermost mantle.

Our seismic model indicates that Poisson's ratio, which is an indicator of crustal composition [e.g., Holbrook *et al.*, 1992; Christensen, 1996] varies with depth from 0.23–0.26 in the

Figure 7. Upper crustal velocity structure (a) Model with velocity isolines (km/s) derived from finite difference travel time inversion. The high-velocity zone (6.3 km/s) correlates with the antiformal core of the uppermost crust of the orogen where ultrahigh-pressure rocks occur. (b) Number of rays traveling through each cell. The central part of the profile (between 80 and 280 km) was covered by sufficient rays and the inverted velocities at depths are reliable. The rays in the interval between 100 and 200 km do not penetrate below the depth of ~5 km due to the high velocity zone (6.3 km/s).

upper crust to 0.26–0.29 in the lower crust. Estimated uncertainties are 0.02–0.03. The composition of the crust of eastern China, including the area of the Dabie Shan orogen, has previously been discussed by Gao *et al.* [1998], Li and Mooney [1998], and Kern *et al.* [1998]. The combined compressional and shear wave model (Figure 9) is consistent with these previous models for an upper crustal composition of felsic metasedimentary and granitic rocks, a middle crust of intermediate (dioritic) composition, and a lower crustal composition of intermediate-to-mafic rocks in the amphibolite to granulite metamorphic facies. There is no seismic evidence for a volumetrically significant amount of high-velocity eclogite within the deeper crust, despite the fact that eclogite is locally exposed within the Dabie Shan [Kern *et al.*, 1998].

8. Discussion

Despite significant collisional convergence in the Mesozoic and the presence of surficial ultrahigh-pressure rocks, only a modest crustal root presently exists beneath the Dabie Shan. The crust thickens from 35 km beneath the Yangtze craton to 41.5 km at the northern margin of the Dabie Shan and thins to 34 km beneath the Sino-Korean craton. The average velocities of the crust beneath the Yangtze craton, the Dabie Shan, and the Sino-Korean craton are 6.35, 6.30, and 6.25 km/s, respectively. Both the Yangtze craton and the Sino-Korean craton have a three-layer crustal structure with velocities of 6.0–6.2, 6.5, and 6.8 km/s. A high-velocity (7.0–7.4 km/s) lower crust, which is common beneath platforms and shields [Holbrook *et*

al., 1992; Rudnick and Fountain, 1995; Christensen and Mooney, 1995], is not present. The seismic velocity beneath the Moho is a typical continental value of 8.0 ± 0.1 km/s. Dong *et al.* [1996] used a portion of these same seismic refraction data to get a preliminary crustal model that differs in several important details from our paper. For example, their model has no upper crustal high-velocity (6.3 km/s) zone beneath the UHP belt (Figure 7), and no Moho offset beneath the Xinyang-Shucheng fault (Figure 9). Our model contains more details than that of Dong *et al.* [1996] because we have modeled the complete data set with a combination of finite difference travel time and 2-D ray trace methods.

The structure of eastern China, including the Dabie Shan, is comparable to highly extended crust, which has an average thickness of 30.5 ± 5.3 km and average crustal velocity of 6.21 ± 0.22 km/s [Li and Mooney, 1998; Christensen and Mooney, 1995; Rudnick and Fountain, 1995]. Recent global seismic tomographic inversions indicate that the lithosphere is significantly thinner beneath eastern China than beneath the Siberian craton, Canadian shield, or Baltic shield [Ekström *et al.*, 1997]. These observations indicate that the lithosphere has been thinned in eastern China, including beneath the Dabie Shan, and that the crust has undergone moderate extension. This interpretation is supported by high heat flow (58–87 mW/m²) and quantitative modeling that suggests a lithospheric thermal thickness of <100 km [Yuan, 1996]. Taking these observations further, Gao *et al.* [1998] and Kern *et al.* [1998] speculate that a mafic (eclogitic) lower crust in eastern China,

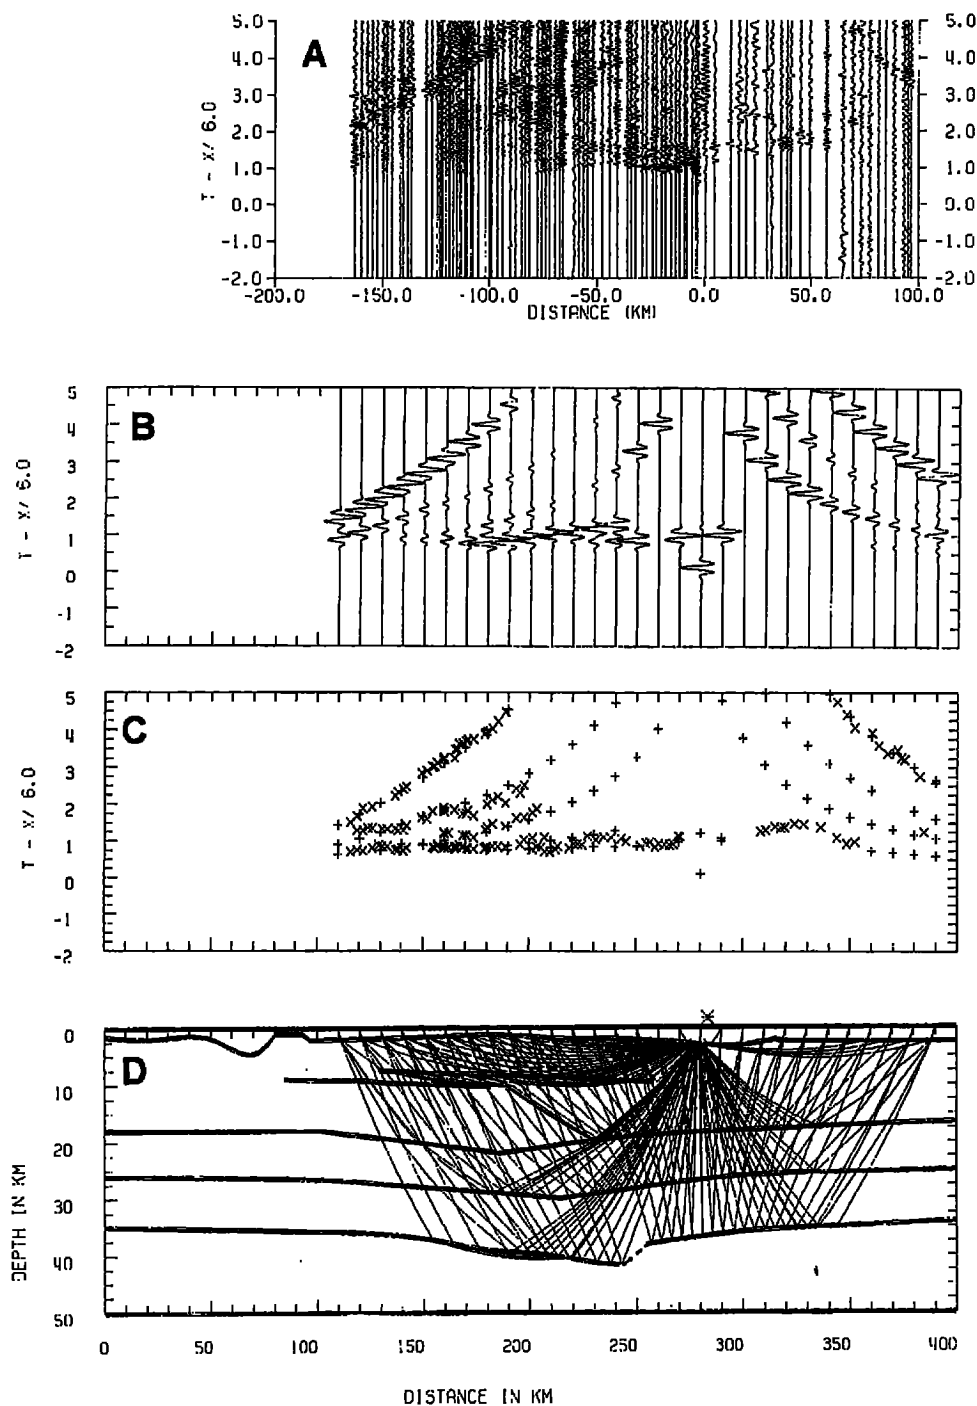

Figure 8. Calculation of ray tracing and 2-D synthetic seismogram and comparison with the observed data of shot point BuT. (a) Record section with normalized trace. (b) Trace-normalized synthetic record section. Amplitudes are generally stronger than observed data because seismic scattering and attenuation have been neglected. (c) Observed and calculated travel times, where crosses and pluses denote the observed and calculated travel times (s), respectively, with a reduced velocity of 6.0 km/s. (d) Ray paths, where asterisk denote shot point.

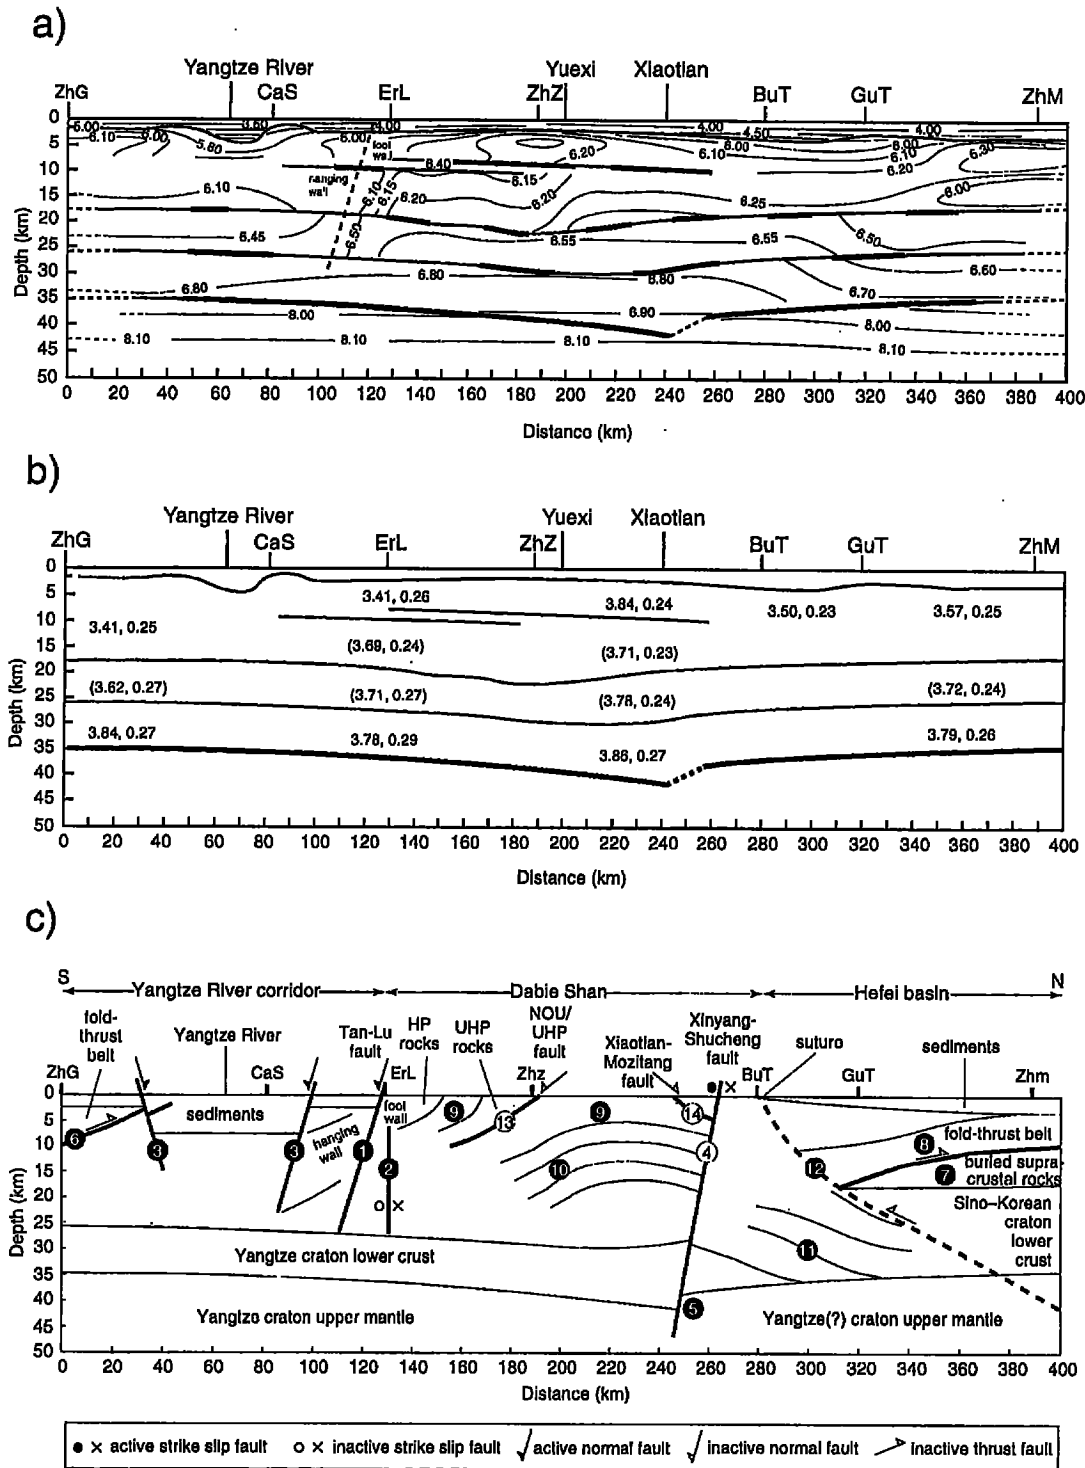

Figure 9. Final 2-D crustal model of the Dabie Shan. (a) *P* wave crustal structure. The velocity of upper crust (0–7 km) is determined from *P_g* using the finite difference inversion. The interfaces were determined by the arrival times of the wide-angle reflection and *P_n* waves from the all eight shots. Dashed line indicates the Moho offset. Velocities are accurate to better than 3%; depth of boundaries is accurate to better than 10% of the total depth [Mooney, 1989]. (b) *S* wave velocity and Poisson's ratio in the crustal structure, which has the same interfaces as the *P* wave model. Velocities and Poisson's ratios denoted with brackets indicate larger uncertainties (~5% in shear wave velocity; ~15% in Poisson's ratio). (c) Geological interpretation of Dabie Shan orogenic structure. See discussion, including key to numbers, in text.

Figure 10. Record section with S wave arrivals (radial component), plotted with reduced velocity 3.50 km/s of shot point ErL. The direct arrival S_g , intracrustal reflection S_1 , and Moho reflection SmS are clearly observed. Additional intracrustal reflections are generally weak and are variably recorded from other shot points. The quality of the S wave data in this record section is typical of the other shots recorded in this study.

including the Dabie Shan, was delaminated and recycled into the upper mantle during Cenozoic crustal extension.

We have combined our seismic model and the geological interpretation of *Hacker et al.* [1998] in a speculative crustal cross section of the Dabie Shan (Figure 9c). Referring to the numbered structural elements in Figure 9c, the active Tan-Lu fault (1) is an east dipping normal fault with a clear seismic signature defined by higher velocities in its footwall. As noted earlier, the conventional interpretation of the Tan-Lu fault is that it began as a Triassic sinistral strike-slip fault [e.g., *Yin and Nie*, 1993]; steep velocity gradients (2) east of the interpreted position of the modern Tan-Lu fault may reflect this older structure. Oblique normal faults that bound the Yangtze River SE of the Dabie Shan (3) can also be correlated with velocity gradients. An active sinistral strike-slip fault near the northern topographic limit of the Dabie Shan, the Xinyang-Shucheng fault (4), has no clear seismic signature within the crust; however, we speculate that it is responsible for the observed Moho offset (5). The seismic velocity structure south of the Dabie Shan may reflect contractional deformation associated with the fold-thrust belt (6). Likewise, we interpret the seismic velocity structure beneath the northern Hefei basin as reflecting thrusting in the hanging wall of the Sino-Korean crust, with middle crustal rocks (8) over supracrustal rocks (7). More speculatively, we tie the homoclinal south dipping foliation and south plunging lineation within the high- to ultrahigh-pressure section exposed in the southern Dabie Shan [*Hacker et al.*, 1995b] to the northward increasing velocity gradient at (9). *Hacker et al.* [1998] described the pre-Cretaceous structure of the Dabie Shan as a crustal-scale antiform formed by warping of the high- to ultrahigh-pressure slab drawn southward out from beneath the Sino-Korean craton. We postulate that northward increasing velocity gradients at (10) and southward increasing velocity gradients at (11) are part of this antiform, which uplifts rocks with midcrustal velocities into the upper crust. This leads further to the implication that the suture between the two cratons is north of this antiform (not at the Moho offset), and we speculatively show it at location (12), dipping north beneath the trace of the isotopically defined crustal suture [*Hacker et al.*, 1998]. Cretaceous normal faults that bound the southern (13) and northern (14) edges of the northern Dabie Shan magmatic-extensional complex have no clear seismic signature.

9. Conclusions

The crustal structure of the Dabie Shan has been determined from a new deep seismic refraction profile. In the shallow crust beneath the exposed ultrahigh pressure (UHP) rocks, there is a broad (50 km wide) high-velocity (6.2–6.3 km/s) zone centered at a depth of 4–5 km and a thin (1 km thick) high-velocity (6.4 km/s) layer at a depth of 8 km. Below 9 km, the middle and lower crust beneath the UHP zone are very similar to the crust to the north and south (i.e., beneath the Sino-Korean and Yangtze cratons, respectively). This suggests that UHP rocks are primarily concentrated in the upper crust (above 9 km depth) of the orogen. Our seismic model indicates that eclogite is not volumetrically significant within the middle or lower crust.

There is only a modest (6.5 km deep) crustal root beneath the Dabie Shan. The thickness of the crust ranges from ~35 km beneath the Yangtze and Sino-Korean cratons to a maximum of 41.5 km at the northern margin of the Dabie Shan. The small variation in depth to the Moho along this 400-km-long profile indicates that the crust involved in the Triassic collision has undergone postcollisional thinning. This has been accomplished by a combination of isostatic uplift, erosion, and moderate crustal extension. An observed Moho offset is likely due to an active strike-slip fault. Much of the Triassic structure associated with the formation of the orogen and UHP rocks has been obscured by post-Triassic events. However, the crustal velocity structure determined for this profile is compatible with a north dipping suture located north of the Dabie Shan (Figure 9c) and an antiformal culmination of UHP rocks in the center of the Dabie Shan (Figure 7).

Acknowledgments. This research was jointly supported by the Natural Sciences Foundation of China and the Chinese Joint Earthquake Sciences Foundation under grants NSFC49374208 and JESF94-031. The fieldwork was conducted with the assistance of X. K. Zhang, B. Y. Chen, X. B. Chen, and the Geophysical Prospecting Center of the China Seismological Bureau. Crustal Structure Beneath Xingtai Earthquake Area in the North China and its tectonic Implication

Chun-Yong Wang, Xian-Kang Zhang, Zhong-Yang Lin, Qing-Ju Wu*

Institute of Geophysics, State Seismological Bureau, Beijing 100081, CHINA

*Geophysical Prospecting Center, State Seismological Bureau, Zhengzhou 450003, CHINA

Abstract Xingtai earthquakes of 1966 occurred in the central region of North China basin. To obtain detail crustal structure and then understand the seismotectonics of Xingtai earthquakes, three deep seismic reflection profiles were conducted in Xingtai earthquakes area in recent years. The CDP stacking sections show the basin and range structure in the shallow crust, a large-scale detachment in middle crust. In addition, a high-angle fault in mid-lower crust is inferred according to the discontinuity and inclination of the reflection events on the sections. The moderate-low angle normal fault in shallow crust, the high-angle fault in mid-lower crust, and the detachment in middle crust have formed a spatial distribution of the faults in Xingtai earthquake area. The junction of the three faults is beneficial to the stress concentration and energy accumulation. The Xingtai earthquakes occurred on this kind of the background in crust. The high-angle fault in mid-lower crust may be the seismogenic fault of the Xingtai earthquakes. The regional compressive tectonic stress in near EW direction and the additional stress produced by the upwelling of magma had jointly acted on the fault to cause the occurrence of the Xingtai earthquakes.

1. Introduction

In March of 1966, five strong earthquakes (Xingtai earthquakes) with magnitude $M > 6.0$ occurred in the Shulu graben, a small narrow basin with a length of 100 km and a width of 50 km in the west-central region of the North China basin (Figs. 1,2). And during the period of 1966-1984, there are over 68,800 earthquakes in this and surrounding regions. Fig. 3 indicates the locations of the earthquakes with $M > 2.8$. Many seismological studies have been conducted since 1966 in the Xingtai earthquake area attempting to understand the seismicity, earthquake source, ground deformation, geologic setting, crustal structure, earthquake hazards and prediction of earthquake in this area.

The seismotectonics of the Xingtai earthquakes, however, is still not clear. For example, the focal mechanisms of the first shock ($M_s = 6.8$) and the main shock ($M_s = 7.2$) are nearly vertical dextral strike-slip (Seismological Bureau of Hebei province, China, 1986), while the epicenters of the earthquakes are

close to a major normal fault in the Shulu graben. After the Xingtai earthquakes, there are the Hejian earthquake ($M_s=6.3$) in 1968, the Bohai earthquake ($M_s=7.4$) in 1970, the Haicheng earthquake ($M_s=7.3$) in 1975, and the Tangshan earthquake ($M_s=7.8$) in 1976 sequentially in the North China basin. It is necessary to obtain a detail crustal structure in order to understand the seismotectonics in these areas.

Several deep seismic sounding (DSS) profiles were carried out in North China basin from late of 1960's to 1980's (see Sun et al., 1986) for the sake of understanding the relation of the crustal structure to the strong earthquakes. The basic outline and some parameters (thickness and average velocity) of the crust were obtained. However, the lower resolution of the DSS profiles to crust prevents the further investigation. Three deep seismic reflection profiles with a total length of about 150 km were conducted in Xingtai earthquakes area in recent years. The interpretation of the reflection profiles is based upon the common depth point (CDP) stack technique. The standard data processing procedure of seismic reflection profile is used. A detail imaging of the crustal structure in the Xingtai earthquake area is obtained.

2. Geologic setting and previous geophysical survey

North China basin, a large-scale Cenozoic rifted basin, is situated in the east of the Sino-Korean platform, and is adjacent to the Taihangshan uplift westerly, to the Yanshan uplift northerly, to the Luxi uplift southeasterly, and to the Bohai sea easterly. It was a stable continental block before Mesozoic and underwent several significant phases of faulting and subsiding in Mesozoic and Cenozoic (Ye et al., 1985; Hellinger et al., 1985). A series of NNE-NEE faults and some of NWW faults interweave and cut the basin into block structure. The Jizhong depression, the Canxian uplift, the Huanghua depression, the Chenning uplift and the Jiyang depression are consecutively distributed from the west to east in the central North China basin (Fig.1). Each large-scale depression is generally composed of grabens and horsts. The Southern part of the Jizhong depression, where most of earthquakes are located in, consists of the Jinxian graben, the Ningjin horst, the Shulu graben, the Xinhe horst and the Nangong graben (Fig. 2).

The first DSS profile in North China basin was conducted in the late of 1960's (Fig.1, Profile a), which extends from the Yuanshi (close to the Taihangshan uplift) to Jinan (close to the Luxi uplift) and passes through the epicenter of the main shock of Xingtai earthquakes. Teng et al. (1974) suggested that the structure along the profile is divided into five blocks by several deep faults extending to Moho, the lower crust is more complicated according to the several seismic phases of the lower crust, and a thin high velocity layer is possibly in the middle crust. After that, several DSS profiles were carried out in North China basin. The basic features of the crustal structure in Xingtai earthquake area and its surrounding (Sun et al., 1986; Zhu et al., 1995) are the three-layer crustal model, the lower average crustal velocity

(6.2-6.3km/s), the thinned crust (30-33km) and the uplifted Moho. Due to the sparse shot points and few number of fold coverages along the seismic profile, the collected data are not sufficient to image the detail crustal structure beneath the Xingtai earthquake area, however.

3. Profile framework

To understand the seismotectonics, obtaining a detail crustal structure beneath the Xingtai earthquake areas is needed. Three deep seismic reflection profiles were successively conducted in Xingtai earthquake area in 1991 and 1992. The locations of these profiles are in Fig. 2. Where profile A, the Ningjin-Xinhe profile, is with a length of 40 km; profile B, the Lincheng-Julu profile, is 55 km long; and profile C, the Renxian-Ningjin profile, is also 55 km.. Profiles A and B pass through the epicenters of the first and main shocks respectively, and Profile C intersects the other two profiles at the first and main earthquake epicenters. These reflection profiles are coincident with three previous DSS profiles, the Yuanshi-Jinan profile (Teng et al. 1974), the Tai'an-Longyao-Xinzhou profile (Zhu et al., 1995, Fig. 1, profile b), and the Renxian-Hejian-Wuqing profile (Sun et al., 1986, Fig. 1, profile c). The coincident scheme can obtain more reliable crustal model beneficial from both reflection and DSS profiles (Mooney and Brocher, 1987).

The observation scheme is an one-side spread and 24-fold coverage using a 96-channel MDS-10 digital seismograph. The geophone group interval is 100 m with a minimum offset of 1000m. The record time is 20s with a sample interval 4ms. The seismic sources are explosive shots below a depth of 25 m in holes, which makes explosion under the ground water level and keeps good excitation condition on the field site.

We have used the standard data processing procedure of seismic reflection profile, which includes the demultiplex, field static correction, pre-processing, deconvolution, velocity analysis, residual static correction, normal (or dip) moveout and migration. The optimal velocity-depth function is generally chosen from a series of stacking velocity in the module of velocity analysis. However, the reliable velocity estimate is only for upper crust (i.e. the two-way travel time (TWT) <4.0s). The deep velocity estimate is provided by the crustal velocity structures from the three DSS profiles. The interpretation was based on the CDP stacking sections and was partly referred to the migrated sections.

4. Crustal Structure

Figs. 4,5, and 6 are the CDP stacking sections of profiles A, B, and C, respectively. These sections indicate that the shallow crust is a typical extension, a result consistent with the seismic reflection

studies of the oil exploration in this area (Xu et al. 1985). The graben and horst structure, asymmetric faulted basin, and listric normal fault are developed in the shallow crust, and laminae in crust-mantle transition (Figs. 4 and 5). The Xinhua fault, the main fault of the Shulu graben, extends in listric shape to below 4.0 s TWT (Fig. 6), where the metamorphic rocks are developed in Paleozoic, and also in early and middle Proterozoic. It controls the stratum distribution in Mesozoic and Eogene, and extends upward to Neogene and Quaternary.

The Moho reflection events clearly appear from 10-11.5 s TWT on these three profiles suggesting a feature of high-energy, well-continuity, multi-cycle and long-duration. These reflections are related to the crust-mantle transition. The ~~different~~^{duration} duration time among these three profiles (Figs. 4, 5 and 6) suggests that the transition is lateral inhomogeneous. Some of reflection events are even too weak to be continuous on the profile B. The depth at the bottom of the transition is 30-32.5 km from the time-depth conversion, which is consistent with the depth of Moho from the DSS profiles. In addition, the reflection events in the section of 13.5-14 s TWT may indicate that local discontinuity exists in the uppermost mantle beneath the Shulu graben.

A set of low-angle reflection events with long continuity and strong energy are illustrated from 2.5-4.5 s TWT in the profiles A and B. The stretch length is about 40 km and it cannot be caused by sedimentary bedding because the sedimentation reflection is shorter. We interpret them as a detachment, which was developed in the crystalline basement and was inclined eastwards from a depth of 5 km at the west to 10 km deep at the eastern part along the profile. The strong reflection events may be due to a mylonite zone in mid-crust. There is no strong acoustic impedance at the depth (Zhu et al., 1995). In general, the strong reflection is difficult to be generated. Based on the laboratory results (Jones and Nur, 1983), the reflection can be observed on the mylonite zone due to its strong anisotropy even though there are no large contrasts in velocity and density. According to the stretching tendency, we suggest that the detachment outcrop 10-15 km to the western end of the profile B, which is confirmed recently by the field geological survey (Ma et al., 1995). This detachment is connected to a shear zone in the Taihangshan piedmont fault belt. Several major boundary faults in shallow part of the Jizhong depression converge to the detachment in listric shape (Ma et al., 1995).

Based on the continuity, energy duration, and inclination of reflection events in mid-lower crust and Moho transition along profiles A and B, and referring the amplitude variation of the wide-angle reflection on Moho (Zhu et al., 1995), we infer that a vertical boundary from the depth of the detachment down to Moho transition exists on the sections (Figs. 4, 5), which respectively passes through the epicenters of the first and main shocks, and it may be related to a high-angle fault. Fig. 7a shows a projection of the earthquake hypocenters ($M > 2.8$) on the profile A with a width of 25 km. Most of the hypocenters with $M > 5.0$ are lain in a vertical belt of about 10 km wide (around Dongwang in Fig. 7a). It seems to be a high-angle earthquake fault in the crust. The existence of the high-angle fault is consistent

with the focal mechanism of the first and main shocks (Seismological Bureau of Hebei province, China, 1986). Consequently, it may be related to the sequential occurrence of the Xingtai earthquakes.

Figs. 4, 5 and 6 indicate that many reflection events in the mid-lower crust are characterized as lamination along profiles, and are strongly deformed. This may imply a possible upwelling of mantle material. The intrusion of magma will generate additional extension stress in the upper crust and heats up the lower crust simultaneously. This will decrease the viscosity and results in dehydration in the lower crust. Then, the dehydrated water goes upward and deposits in the middle crust. The extension stress, the compound effects of heat and water will impel a detachment formation. This feature is similar to the two-layer rheologic model (Sibson, 1982). In fact, the detachment is a transition with certain range. The strong earthquakes generally occur in this zone. Fig. 7b is similar to Fig. 7a, except that the projection is on the Profile C. The standard error of the earthquake locations is less than 5 km. Note that 85% of earthquakes with $M > 5.0$ are at depths of 10 km and 20 km, and few of earthquakes are below 25 km in depth. Conservatively speaking, the transition zone is between depths of 10 and 25 km.

Profile C lies in the Shulu graben and parallels almostly to Xinhe fault. The section within 0-4s TWT (Fig. 6) shows that the Shulu graben may be divided into three parts by a set of NW-trending faults. These shallow faults extend to the top of crystalline basement with a lower angle. Many reflection events with lamination and deformation appear on the section of 4-10s TWT, which extend upward from the bottom of the crust. The arched events at about 4.0 s TWT are related to the detachment on profiles A and B.

The reflections below the arcuate events crossing each other (Fig. 6, 4-7 s TWT) are called as crocodiles (Meissner et al. 1992). After doing the migration process on the data processing procedure, the arcuate and crocodiles events still exist on profiles C. It infers that there is really a special structure in the middle crust. The crocodiles indicate the shorten process of the crust in compressed zone. This feature exists in the Basin and Range province in the western United States, and is interpreted as a product of the compression before the extension (Klemperer et al., 1986). If it was the way for the Xingtai earthquakes area, there would be a compression before the formation of the North China basin.

Based on the imagings of three reflection profiles and referring the velocity structure from Teng et al. (1974), Zhu et al. (1995), and Sun et al. (1986), the three-dimensional sketch of the crustal structure in the Xingtai earthquake area is presented in Fig. 8. There are two grabens with moderate-low angle normal faults and dense reflection events and a horst with few reflection events in upper crust and a high-angle fault in mid-lower crust. A long stretch of detachment is in the middle crust, and a low velocity zone is beneath the detachment. The junction of the three faults is beneficial to the stress concentration and energy accumulation (Song et al., 1993). There are laminations in the mid-lower crust, which indicate the upwelling from the mantle. The upper plate above the detachment slipped eastwards due to the effect of extension and gravity in Cenozoic.

5. Discussion and Conclusion

The deep seismic reflection profiles conducted in Xingtai earthquake area show more clear crustal images than that produced before. This is attributed to the data with high signal-noise rate (due to the field conduction in winter) and the multi-stack scheme, although the number of fold coverage on the profiles is not very high. The site conditions are ideal and keep good ground coupling for the geophones. The crustal structure from the reflection profiles is basically consistent with that from the coincident the DSS profiles, in which the complicated lower crust, the lower average crustal velocity (6.2-6.3km/s), the thinned crust (30-33km) and the uplifted Moho characterize the Xingtai earthquake area.

The inconsistency of the seismotectonics between the focal mechanism and the field geological survey may attribute to the discrepancy of the different geological events in the time and space domains. The discrepancy in the space domain is mentioned in this paper. As for the discrepancy in the time domain, since the neotectonic movement of North China plain, the sedimentary tectonics and the stress pattern has been changed considerably. A trending-EW seismic reflection profile of oil exploration, which passes through the Xingtai earthquake area and reaches the Taihangshan piedmont, indicates that a thrust fault inclines eastwards and cuts in the Quaternary stratum and its frontier has been strongly deformed. (G.D. Liu, 1995, private communication). The average P and T axes of tectonic stress field in North China is nearly horizontal, trending NEE-SWW and NNW-SSE, respectively (Xu et al., 1992). These implicate that the Xingtai earthquake area has undergone regional compression trending near EW at the present time. Consequently, the Xingtai earthquakes occurred under the environment of the crustal structure beneficial to the stress concentration and energy accumulation.

Based on these deep seismic reflection profiles, and combining with results of other geophysical survey, we got the following points about the seismotectonics of Xingtai earthquake area:

1. The moderate-low angle normal fault in upper crust, the high-angle fault in mid-lower crust, and the detachment in middle crust had formed a spatial distribution of the faults in Xingtai earthquake area. The detachment may play an important role in the tectonics of Cenozoic extension in North China basin. The junction of the three faults is beneficial to the stress concentration and energy accumulation.
2. The high-angle fault in mid-lower crust can be thought as a seismogenic fault of the Xingtai earthquakes. This fault may exist before the Cenozoic extension, and is reactivated recently. The shear stress acts on the fault to cause dextral slip.
3. The modern regional tectonic stress field and the additional stress field produced by the intrusion of magma had jointly acted on the fault to cause the occurrence of the Xingtai earthquakes. The major action is the regional tectonic stress.

Acknowledgments This research was jointly supported by the National Scientific and Technological Committee and the State Seismological Bureau (SSB), China, under the grants NSTC85-907-02-01 and SSB85-02-01. The authors greatly appreciate the valuable suggestions about the field work and data interpretation by R.S. Zeng, G.Y. Ding, Y.T. Chen, J.W. Teng, G.D. Liu and Y.S. Zhang. The field work of this project was conducted by the group in SSB of China. Data collection and processing were assisted by the Geophysical Prospecting Bureau of the General Corporation for Oil and Natural Gas, China. We also wish to express our sincere thanks to them.

Chapter 1 Introduction

The Golmud-Ejin geoscience transect interdisciplinary research is a key project supported jointly by the Ministry of Geology and Mineral Resources (MGMR) of China and the National Natural Science Foundation of China (NNSFC). It is the second geoscience transect compiled with financial support of the MGMR and NNSFC following the completion of the Yadong-Golmud geoscience transect. The main purpose of the transect is to study the structure and formation mechanism of the crust and lithosphere of the transect corridor and its neighboring areas, to study the kinematic process and dynamic mechanism of the formation and deformation of the continental lithosphere, to probe into the formation of the northern boundary of the Qinghai-Tibet plateau and its dynamic relation with the collision of the Indian and Eurasian plates, and to ascertain the deep-seated tectonic background of the distribution of mineral resources and the occurrence of natural hazards in the study region.

Upon completion this transect will be linked with the early-completed Yadong-Golmud transect to form a long geoscience transect running from south to north across the western continent of China, which will successively displays the entire structure of the continental lithosphere from the Qinghai-Tibet plateau to the Beishan Mountains in a completely new form and make it possible to study the uplift mechanism of the Qinghai-Tibet plateau and the deep-seated geological background influencing the distribution of mineral resources and natural hazards from an analysis of the formation of the continental lithosphere and the kinematic and dynamic process of deformation. Therefore this long geoscience transect is bound to become a typical transect of the continental lithosphere in western China or Asia and even the world.

There are four items under the Project: geology, geophysics, geochemistry and comprehensive research. In 1992 the Project was approved by the Department of Science and Technology (DST) of the MGMR and then the research began. The responsible organizations are the Lithosphere Research Centre (LRC) of the Chinese Academy of Geological Sciences (CAGS) and the Institute of Geology (IG) of the MGMR. The main participating organizations (which refer to the organizations responsible for various special subjects under the Project) include the 562 Comprehensive Research Team of the CAGS, China University of Geosciences (Beijing), Changchun College of Geology, Institute of Geology, Academia Sinica and Chengdu College of Geology. In addition, the Institute of Geology, Bureau of Geology and Mineral Resources of Gansu province took part in the work of the Tectonics Group, the Second Geophysical Prospecting Party of the MGMR took part in the field work of deep seismic sounding and the Institute of Geophysics of the Academia Sinica took part in the indoor processing of deep seismic data. The main participants totaled about 40, most of whom were professor researchers and associate professor researchers.

Through four years of coordinated efforts, we completed the field surveys and laboratory work. On the basis of the first items of work and the comprehensive research of the last item, we accomplished the compilation of the transect and its explanatory notes, studied the terrane

division, features of major faults and tectonic evolution in the transect corridor, made geophysical interpretations and geodynamic analysis and studied the existing problems.

The maps of the transect were compiled by the following relevant special subject groups.

Index Maps: Yao Peiyi

Geological Strip Map: Chen Bingwei and Wang Yanbin

Gravity Strip Map: Meng Lingshun, Gao Rui and Guan Ye

Magnetic Strip Map: Yu Qinfan and Lou Hai

5–10 km Factual Cross Section: Liu Xun and Chen Bingwei

Geophysical Interpretations: Gao Rui et al.

Interpretative Cross Section: Liu Xun, Gao Rui and Deng Jinfu

Time-Space Flow Chart: Liu Xun and Wei Guangming

Map of Block Migration: Dong Xuebing

Dynamic Model: Gao Rui and Wu Gongjian

Legends: Liu Xun and Yao Peiyi

The explanatory notes were written by Liu Xun and Gao Rui, the explanations of relevant maps were provided by the related groups of special subjects and the preface and concluding remarks were written by Wu Gongjian and Wang Naiwen.

We are grateful to the leaders and persons in charge of the MGMR Department of Science and Technology and the NNSFC Geoscience Division for their direction during the research..

2.5. Geophysical Interpretations

This map represents parameters of major physical properties in detail, to give a comprehensive interpretation of lithospheric structures in the Golmud-Ejin geoscience transect and describes the downward extension, assemblage and system of the major tectonic elements such as faults on terrane boundaries. The detailed description will be found in Chapter 4.

The Moho depth along the whole transect was determined by deep seismic sounding and checked by inverse interpretation of gravity profiles. To make the map seen distinctly, data arrays are used to represent interfaces and velocity structures of the crust and 2-D variation curves of the velocity are illustrated as an insert map in Chapter 4.

The electrical structure of the transect was clarified based on the inverse results of MT and shown by a columnar diagram of electrical resistivity vs. depth with the resistivity values (unit: $\Omega\cdot m$) printed nearby. The two-dimensional method was used to interpret lateral variation of the electrical structure and the result is shown in this booklet.

Characteristics of the lithospheric geotemperature field of the major terranes were inferred in terms of measured geotemperature curves and expressed by temperature/depth curves. Two-dimensional variation of the geotemperature field determined by one-dimensional results is shown

in Fig.4-2.

To reduce the map's burden, the density structure is not shown in the map but discussed in Chapter 4 instead.

2.6. Interpretative Cross Section

This map represents the ultimate result of this research project on the basis of integrated analyses combining geological, geophysical and geochemical data acquired in the course of the research work. The compiled section map summarizes the knowledge of the material composition, structure and evolution of the crust in this transect. The materials and data used for the map compilation were mainly taken from the following work.

(1) Surface geological investigation

This investigation presented ideas concerning surficial structures of the crust by means of the 5–10 km geological section. It was conducted through comprehensive analyses on stratigraphy, biotas, sedimentary formations, magmatism, metamorphism and tectonic deformation of different tectonic units and terranes at surface. This work describes the components, vertical and horizontal variations of the deep or shallow structures shown in the map.

(2) Geophysical investigation

Integrated analyses of gravity, magnetic, electrical, seismic, geothermal data and surface waves were done and the map of geophysical interpretations was compiled, which provides a basic frame for interpreting the structure of the deep crust by using this transect. In consideration of the ambiguity of geophysical data interpretations, more geological data should be taken advantage of in order to give more realistic results.

(3) Geochemical investigation

Analyses were carried out for the composition and metamorphic state of the deep crust (primarily the middle and lower crust) based on typhonic rocks and deep inclusions observed on surface and experimental results of temperatures and pressures for the formation of deep materials along with such data as density, velocity and temperature provided by above geophysical fields. This map mainly shows material compositions, while various symbols denoting metamorphic processes are overprinted to illustrate their spatial distributions and variations and the relationship with tectonic evolution.

A distinctive feature presented in the map is the apparent vertical and horizontal inhomogeneity of the crustal composition and structure in all zones traversed by the transect. Vertically, layering of the crust is exhibited; horizontally, different crustal structures are seen from segment to segment of this transect not only in layering and thickness, but also in material composition.

It can be seen in the upper crustal structure that the five ascertained terranes are markedly distinctive in their structures, indicating that these terranes have different evolution histories. This will be discussed in detail later. The map also shows that the tectonic events occurred in the upper crust have an evident orientational nature. On the whole, the Beishan area north of the Hexi

Corridor basin is characterized chiefly by large-scale napping and detachment from north to south; while the Kunlun area south of Qaidam mainly by detachment and napping from south to north. The Qilian Mountains are located between them and thus characterized by southward and northward napping with the south-central Qilian area as the core (the front of the northward napping even reaches the Kuantanshan fault). As a result, a set of nappe systems were formed in the upper crust along the whole transect with Qaidam and the Dunhuang block in the north Hexi Corridor as the core and there also occurred a series of related strike-slip faults. It should be pointed out, of course, that all these phenomena resulted mainly from the crustal stress ever since Cenozoic and are closely related to the uplift of the Qinghai-Tibet plateau and the Qilian Mountains.

Currently available data show that the middle and lower crust within the transect also varies laterally. Geophysical and geochemical studies of this research revealed that the middle and lower crust here can be horizontally separated into three segments.

(1) The Beishan area

The thickness of the crust is generally $40 \text{ km} \pm$ and the average velocity is 6.29 km/s . There is no clear mountain root. The upper crust is $14\text{--}17 \text{ km}$ thick and the interval velocity increases from $5.85\text{--}5.93 \text{ km}$ to $6.10\text{--}6.17 \text{ km}$. Underlying is a low-velocity layer, $7\text{--}9 \text{ km}$ thick, with a velocity of 6.0 km/s . However, the velocity contrast of the low-velocity layer in this area is not very large. Correspondingly, magnetotelluric sounding discovered a clear low-resistivity layer, where lies the major detachment surface resulted from a series of aforesaid northward napping events. The interval velocity of the midcrust is 6.5 km/s and the thickness is $7\text{--}10 \text{ km}$. It consists primarily of grano-dioritic rocks (shown in the map as granitic composition plus dioritic lenses) and exhibits amphibolite facies metamorphism. The interval velocity of the lower crust is $6.9 (6.75\text{--}7.2) \text{ km/s}$ and the thickness is $6\text{--}10 \text{ km}$. The interval velocity of the top layer of the upper mantle is 8.2 km/s . It is considered that the lower crust consists mainly of dioritic rocks and has granulite facies metamorphism. In general, the Beishan area has relatively thin crust and no clear low-velocity layer. The lower crust is thinner while the middle and upper crust are thicker in this area, featuring a crustal structure of a stable Meso-Cenozoic continental crust region. In the area south to Yemajing, the Moho begins to dip gently towards the south and the crust thickens gradually.

The temperature of the top mantle, calculated based on geothermal data, is $600^{\circ}\text{--}700^{\circ}\text{C}$, which is obviously lower than that in the Qilian area of south.

(2) The Qilian area

The total crustal thickness is $55\text{--}70 \text{ km}$ and the average velocity of the crust is 6.35 km/s . The upper crust is $23\text{--}26 \text{ km}$ thick and the interval velocity increases downwards and is up to $6.2\text{--}6.3 \text{ km/s}$. A clear low-velocity layer rests underneath it with an average velocity between 5.8 km/s and 5.9 km/s . Its thickness varies between 9 km and 10 km . The available information shows that a series of nappe structures in this area converge downwards near the base of this low-velocity layer and it is naturally a stress-concentrated position responsible for the northward and southward

napping and detachment of the Qilian Mountains. It is shown by MT that this layer is composed of a set of low-resistivity zones and epicenters of modern earthquakes are also concentrated near the top of this layer. This probably results from intensive mylonitization caused by structural gliding along this layer. The average interval velocity of the midcrust in this area is 6.35–6.5 km/s and the thickness ranges from 8 km to 11 km. This part of the crust is inferred to be granitic with granulite facies metamorphism. The average interval velocity of the lower crust is 6.8 km/s and the thickness is 20 km \pm . It can be inferred that this crustal layer consists mainly of grano-dioritic rocks and has high-pressure granulite facies metamorphism. Some eclogites and high-pressure metamorphic rocks occurring in the southern and northern Qilian areas are likely related to this layer. These rocks were outcropped when this crustal layer was pushed upwards.

Unlike other areas, the crust in the Qilian area is very thick, which is believed to be caused by a special mountain root belt. This root belt is predominantly dioritic and probably contain a large amount of eclogites and lenses of pyrolites. It is characterized by eclogite facies metamorphism. The belt has its thickest part around the area from Har Lake to Juhongtu, up to 18–20 km, and it gets thinner remarkably towards the southern and northern sides until it is absent at last. Because of this mountain root belt the southern Qilian area becomes strikingly distinctive from other areas for its great crustal thickness.

In the meanwhile, the temperature at the top of the upper mantle is much higher than that of the both sides of this area, which is evaluated to be as high as 850°–950°C. This indicates that there exists a hot mantle around here. The crustal structure of the whole Qilian area is characterized by a tectonically active belt.

(3) The Qaidam area

The crust in this area is 50–53 km thick in total and thickens both southwards and northwards. The average velocity of the crust is 6.15–6.17 km/s. Based on the velocity structure it can be divided into the upper and lower parts with no middle one, which corresponds to interval velocities of 6.4–6.5 km/s. The upper crust is 30–35 km thick and its velocity changes from 5.7 km/s to 6.3 km/s. This part can be further divided into two layers. The upper one is a sedimentary cover and crystalline basement, while the lower is a granitic-grano-dioritic layer with greenschist to low-grade amphibolite facies metamorphism. In the middle of the upper crust, there exist a set of low-resistivity zones detected by MT, which probably indicates a detachment-nappe belt under the Qaidam basin. The lower crust is about 15–20 km thick and its interval velocity ranges from 6.6 km/s to 6.8 km/s. It consists chiefly of intermediate rock series and thickens evidently towards the mountain chains on both sides of the basin. The temperature of the top mantle is also rather low, calculated to be 500°–600°C, which represents a cool mantle in this area. The facts described above actually represent the features of the crustal structure in an old stable region and these features differ greatly from those of the mountain chains on both sides of this area.

The diversity of the crustal structure within the transect is a composite product of various geological effects during a long geological history. However, it especially reflects the present geological state. Some historical events, such as the opening, subduction and collision of plates,

could find their marks merely at several depths or in varying degrees. Especially the Paleozoic subduction zones and variation of the crustal structure of the plate on both sides of the Paleozoic collision zone can even hardly be identified at present due to the reworking in the period of 200 Ma ever since the Paleozoic.

The faults in this transect, including those on the terrane boundaries, ductile shear zones formed later, large nappe structures, strike-slip faults and some deep-seated faults recognized in terms of geophysical data, are all illustrated in the cross section in a suitable form.

Those faults possess the following characteristics, which have been learnt on the basis of the information currently available.

(1) Most of the faults have their long active periods, especially the faults on the boundaries of some terranes. Some of them were crustal convergence zones in the Caledonian and Variscan ages and became active again in the Mesozoic due to subsequent new tectonic stresses.

(2) Except some old crustal convergence zones identified in the middle and lower crust, most of the faults, especially the Mesozoic and Cenozoic ductile shear zones and large detachment and nappe structures, do not reach or cut to Moho surface, but are terminated somewhere around the top or base of the midcrust, or disappear in the low-velocity layers of the midcrust.

(3) It is indicated by existing data that these faulting events, especially those of the Cenozoic, are obviously characterized by shearing and strike-slipping. Induced by these events, eruptions of basic magmas originating from the upper mantle have taken place (the northern Qilian area is typical of this case) and there are also a series of modern earthquake activities.

(4) What should be emphasized is the Kuantanshan fault. The reflection survey revealed that this is a listric fault with the upper part steeper than its lower part and absent at the top of the lower crust, clearly exhibiting a nature of northward napping. Regionally, this fault is regarded as the east extension of the giant Altun strike-slip fault. We, therefore, proposed that it is a part of the Altun fault and a crustal convergence belt closed in the Late Paleozoic, along which strong overthrusting and napping occurred again in the Mesozoic and Cenozoic eras. Especially since the Cenozoic this area is characterized by large-scale sinistral strike-slip movement and becomes a major belt of seismic activity in the present day.

Details will be given in Chapter 3 to describe the specific features of all above-mentioned faults.

Chapter 5 Concluding Remarks and Unsolved Problems

Valuable information and data have been gained by combining geological, geophysical and geochemical techniques in the research of the Golmud-Ejin geoscience transect and a map was compiled in light of the unified requirements stipulated by the ICL. The research shows the amalgamation, accretion and formation of the lithospheric blocks in the Qinghai-Tibet plateau and the Beishan orogenic belt. It also shows the structure and composition of the lithosphere and the kinematic process and deep dynamic mechanism of its tectonic evolution and deformation. The research has provided a deep geological basis for hunting more mineral resources, reducing geological hazards and protecting environment. This transect, when connected with the Yadong-Golmud geoscience transect, is of particular significance to understand the uplift of the whole Qinghai-Tibet plateau. Compared with the Yadong-Golmud transect, this research project involves more tasks and has employed some new methods, including: (1) a subvertical reflection seismic profile (COCORP), which is about 100km long; (2) an intensive geochemical research; (3) tomography and remote-sensing technique; (4) digitization of geological information and computer-aided map plotting; (5) integrate researches combining geochemical and geophysical investigations along with studies on tectonics, and compilation of a vertical geological interpretive section; and (6) animation of terrane movement.

Major achievements of the research are as follows.

(1) For a long time, the frontal fault of the Qilian Mountains was regarded as the northern boundary of the Qinghai-Tibet plateau. However, an inclined reflection seismic phase was found on the reflection profile in the time interval from 5 sec. to 9.5 sec. and continues downwards to the lower crust or even to the Moho, which has also been confirmed by other geophysical methods; whereas the frontal fault of the Qilian Mountains has relatively short extension, terminating in the low-velocity layer at the base of the upper crust. We, therefore, concluded that the newly discovered fault — the Kuantanshan fault should be the northern boundary of the plateau.

(2) Eclogites have been found on the northern margin of the Qaidam basin, indicating that this area is a high pressure-ultrahigh pressure metamorphic belt and probably the west extension of the Sulu (Jiangsu-Shandong)-Dabie high pressure metamorphic belt. Moreover, this research ascertained that the northern margin of the basin is also a giant ductile shear zone.

(3) The Qilian mountains had their orogenic stage in the Middle-Late Jurassic and were involved in the extensive uplift of the Qinghai-Tibet plateau following denudation and planation in the Paleozoic, superimposed deformation in the Mesozoic and rejuvenated orogeny in the Pleistocene. Reflection seismic survey shows that the Tertiary is covered by older strata, which again indicates that the thrusting and overlapping were active in the Cenozoic.

(4) The uplift of the Qilian mountains can be represented by a multifactor model of a bottle-mouth type: thrusting and overlapping were caused at first by two-directional compression to force the crust to be folded and then deep materials were added to the lower crust to make this part of crust thickened.

(5) The above model was tested by tectonic stress field simulation and it is found that the present Qilian Mountains can be successfully modeled only in the case that the applied force on the north side is greater than that on the south. This suggests that the effect of the India plate has been remarkably lessened here.

(6) The Beishan structural belt is characterized by apparent thrusting and napping from north towards south and composed of a set of rootless sheets.

Obviously these ideas have yet to be further proved. Besides, owing to the time limitation, particular location of the study area and limited funds of this research work, there are still some problems to be studied.

(1) Reflection seismic survey proved that the Kuantanshan fault, which traverses the Hexi Corridor basin, is a thrusting fault extending downwards to the middle and lower crust. It is possibly the principal boundary fault of the northern margin of the Qinghai-Tibet plateau. Correspondingly, the basic features of the Qilian Mountains in the orogenic process are very similar to those of the Himalayas on the southern margin of the Qinghai-Tibet plateau and, furthermore, both of them have almost the same time limits in their development after the Oligocene. The Kuantanshan and Altun faults probably belong to the same structural system and we deduce that the former is the east extension of the latter. This idea, however, has not been confirmed by the deep reflection profile across the east of the Altun and Qilian Mountains yet, so we are not able to make a final conclusion in this respect from the viewpoint of regional tectonics. Likewise, we have used only refraction data at present to infer the northern margin of the Qaidam basin as a steep north-dipping thrust fault and made only a tentative discussion regarding the downward extension of the fault in the Kunlun area because no reflection seismic data are available. In one word, characteristics of the deep structures in the major areas or segments of the transect corridor cannot be further clarified until more deep reflection data are acquired.

(2) The present layer model of crustal materials was built primarily based on velocities and densities obtained in geophysical investigations and general experimental petrological data, but lithochemical features and other geophysical information of the transect corridor and neighboring regions were not effectively utilized. This is also because special and detailed geochemical studies could not be conducted in this research. There are still more problems with the model, such as how the layering of the crustal materials was figured out and what influence the material layering will exert on the present crustal uplift and tectonic events now that the model represents the present state of the materials. It is noticed that Cenozoic pyroclites were found in the Kunlun and Qilian Mountains and that ultrahigh pressure metamorphic rocks (eclogites) found on the northern margin of the Qaidam basin, so a special comprehensive geochemical and geological research project seems necessary for the study of their deep occurrence and the mechanism of their emplacement up to the surface.

(3) Some assessment reports have reckoned that the uplifting and orogeny of the northern margin of the Qinghai-Tibet plateau were the events mainly in the period from the Pliocene through to the Cenozoic, but the assessment could not be done stage by stage as in the case of the

Himalayas due to lack of systematic dating and quantitative analytical data. For this reason, we need to conduct quantitative analyses and systematic dating for uplifting terranes (e.g. the Qilian and Altun Mountains) and frontal basins of mountains (e.g. the Hexi Corridor basin and the frontal basin of the Altun Mountains). We have proposed an orogenic model of the Qilian Mountains by simulating the structural stress field, i.e. bi-directional compression (the northern component larger than the southern one) plus southward and northward thrusting and napping along the intracrustal detachment layer (the low-velocity and high-conductivity layer). We think this model was built on good grounds. Then the orogenic process of the Kunlun Mountains tends to be an important problem concerning the orogenic mechanism of the Qinghai-Tibet plateau.

(4) As for the analysis of historical tectonics we hold that the transect corridor and adjacent regions are separated into different parts belonging to different plates or terrane groups by some small Precambrian-Early Paleozoic ocean basins (e.g. the northern central Qilian fault and the Shibanzing-Xiaohuangshan fault). A further question would be how these small ocean basins are related to the large global ocean basins and how these plates or terrane groups are related to the large global plates both in time and in space.

(5) It is commonly considered that the transect corridor and adjacent regions witnessed two subduction-collision events in the Late Paleozoic besides the Early Paleozoic. Calc-alkaline magmatic activity can be the convincing evidence of the collision. Nevertheless, this understanding is short of such evidence as syntectonic ocean crust rocks (typical ophiolite) and subduction complexes (accretionary wedges). The Permian alkaline granite belt in the northern Beishan area is part of the gigantic magmatic belt stretching from Inner Mongolia to Junggar, which is generally regarded to be related with rifting, but an interesting question is what is the relationship between this belt and the subduction-collision. All these problems remain to be solved in our future researches.

Abstract

First P arrival time data from 266 local events and 14 borehole shots were used to determine the 3-D crustal structure beneath the seismically active Western Yunnan region in southwest China. An inversion algorithm of the grided model is used to model the entire crust. Although the 3-D model from the inversion is coarse due to the large station spacing in the area, some significant insights are obtained from the result. The final model is quite complicated, which may indicate the evolutionary history of different tectonic units in the study area. At a depth of 41km velocity differs on either side of the Red River fault. The lower mean velocity (about 6.2-6.3km/s) of the crust, and the negative velocity anomaly of the mid-crust in the area are consistent with the tectonically active area. The seismically active zones in the area are generally related to a negative anomaly in the mid-crust, and to a positive anomaly in the upper crust. This may imply that earthquakes occur in area of the upper-middle crust having positive anomaly, and above the negative velocity anomaly zone which may play a role in earthquake-generation. In the region between Baoshan and Dali, the negative velocity anomaly in the lower crust is consistent with the weak energy reflection from the Moho at Baoshan shot-NE and the high heat flow values may be related to the magmatism in the region of the Tibet-Yunnan Fold System.

Introduction

Yunnan province in southwest China is close to the China-Burma boundary, and at the northern end of the Red River fault, where there are numerous faults with a northerly and northwesterly trend. These faults are accommodating regional east-west crustal extension and north-south shortening. The Red River fault is considered a deep structural discontinuity associated with the collision between the Indian and Eurasian plates (Molnar and Tapponnier, 1975; Allen et al., 1984). The Western Yunnan is a seismically active region. Since 886 AD, more than 200 earthquakes with magnitude $M > 4.0$ have occurred, among them 22 events with magnitude 6-6.9, and 4 earthquakes with magnitude $M \geq 7.0$. The largest event is the Yongsheng earthquake of $M 7.5$ in 1511. The latest is the Lijiang earthquake with $M = 7.0$ in 1996. The State Seismological Bureau (SSB) of China has conducted a number of investigations on seismology, tectonics and crustal structure for over ten

years in the Western Yunnan Seismic Experiment Site (WYSES), which is located at the geographical coordinates of 24.5-27°N and 99-101°E. A broad field of earthquake study has been started with China-U.S. seismological cooperation, and the project of crustal seismology in China has had produced fruitful results (e.g., Kan et al., 1986).

The Kunming Telemetry Seismic Network (KTSN) established in early 1980 is monitored with automatic detection and real-time processing of the incoming signals. The establishment of the network is aimed towards the fast response to the earthquake hazard and the study of seismology. There are 18 seismographic stations in the Western Yunnan. Since 1982, a considerable amount of seismic records have been obtained in the Kunming processing center. In addition, two projects to collect the deep seismic sounding (DSS) profiles were conducted successively in the Western Yunnan area and its vicinity in 1982 and 1987. The data from the DSS profiling were interpreted and 2-D crustal structure models along each profile were presented (Hu et al., 1986; Lin et al., 1993). Six fan profiles in the projects give the ray path coverage of the Western Yunnan area to a degree (Fig. 5), the data have not been exploited until recently. An attempt is made in this paper to obtain a 3-D model in the Western Yunnan based on the first arrival time data from the local earthquakes recorded in KTSN and the DSS profiles (in-line and off-line). We noted that the depth extent of local earthquake tomography models is generally limited by the maximum earthquake focal depths in the area. Therefore, the 3-D model determined in this study will be coarse due to the large station spacing.

The method of determination of three dimensional velocity anomalies under a seismic array using P arrival times from local earthquakes is first presented by Aki and Lee (1976). Kissling (1988) has been described the ACH-inversion (Aki and Lee, 1976) in detail, which is based on the block model. The travel time inversion of local P arrival is a coupled hypocenter-velocity inversion, and must calculate simultaneously the hypocenter corrections and the velocity corrections by minimizing the global travel time residual of a large number of the events (Pavlis and Booker, 1980). After the approach of Aki and Lee (1976), some developments in the representation of structure and the ray path and travel time calculation have been presented, such as the grid model of Thurber (1983), and the 'no-block' approach of Tarantola and Nercissian (1984). The model, including the Conrad and Moho discontinuities (Zhao, 1991), the approximate ray-tracing scheme (Thurber and Ellsworth, 1980), the nonlinear inversion (Koch, 1985), and the combination of P and S velocity structure (Eberhart-Phillips, 1990), has been developed. Walck and Clayton (1987) have inverted 'pure noise' synthetic data to assess the level of uncertainty in the model. The recent alternative approach to the ray tracing problem is the finite-difference method of Vidale (1990).

Geologic Setting and Previous Geophysical Results of the Study Area

The study area is a triple junction zone of the tectonic units separated by the Jinshajiang fault, the Red River fault and the Xiaojinhe-Lijian fault, and bounded by the Yangtze Platform to the east, the Songpan-Ganzi Fold System to the north, and the Tibet-Yunnan Fold System (i.e. the Sanjiang Fold System) to the west and

southwest. The Songpan-Ganzi Fold System and the Tibet-Yunnan Fold System belong in the Qinghai-Tibet Fold System (Fig. 1). These blocks are different in the history of their development, and caused the region to form a complicated tectonic zone with a variety of structures having different evolution and a high seismicity (Chen et al., 1987). The study area has been subjected to extension and pulling-apart which resulted in the formation of a relatively depressed taphrogenic zone over a background of overall block uplifting and upper mantle upwelling. Many active faults are distributed between the taphrogenic zone and the high mountains. The relief is higher to the northwest and lower to the southeast, with valleys down to 1500m in some places and mountains up to 5500m, cut by a series of rivers originating on the Tibet Plateau.

In the study area, the boundaries between the main tectonic units are generally the major faults which are as follows (Fig. 2): the Red River Fault, the Chenhai fault, the Xiaojinhe-Lijiang fault, the Jianchuan fault (i.e. the Jinshajiang fault), the Qiaohou fault, the Lancangjiang fault, the Nujiang fault and the Longling fault. Based on the dislocated drainage system, Allen et al. (1984) assigned a possible right-lateral dislocation of 5.5km to the Red River fault during the Quaternary. Most boundaries are the seismically active belts, where strong earthquakes occurred. However, the Quaternary activity of the Lancangjiang fault, a large fault close to the Red River fault, appears to be less seismically active than in earlier geological times. The modern seismotectonics is controlled by the regional stress field with near NS direction and local stress field with near EW direction (Fig. 3).

The DSS profiles provided seismic data having high quality due to the high signal-to-noise ratio and large amount of explosive charge (>2000kg) in each shot. The interpretation of the DSS profiles show that the crustal structure in Western Yunnan is a 3-layer model (Hu et al., 1986; Kan and Lin, 1986; Lin et al., 1993), where, in general, the upper crust is a homogeneous or weak gradient layer, the middle crust is a homogeneous layer, and the lower crust is generally a gradient layer, while the gradient varies considerably over the area. The lateral variation of the velocity structure indicates that the distinct difference in the velocity structure exists among the main tectonic units, and the boundary between the tectonic units is consistent with the major fault on the surface. The mean velocity of the crust is lower (6.20-6.30km/s). The general trend of the Moho variation is that the interface deepens from southeast to northwest. The depth of the Moho increases from 38.5km in the south of the study area to 52km in the north.

The Bouguer gravity anomaly in the Western Yunnan decreases from -220 mgal in the southeast to -365 mgal in the northwest. The NNW-trending gravity anomaly belt with a gradient of 1.1mgal/km exists to the north of Dali. The remnant gravity anomaly shows that the Red River fault is located at the boundary between the positive and negative anomalies. The high conductivity layer in the upper mantle spreads with variable depth from 60 to 120km (Institute of Geology, SSB and Seismological Bureau of Yunnan Province, China, 1990).

The terrestrial heat flow is quite high in Western Yunnan (Fig.4). Fourteen heat flow values were obtained in the Western Yunnan and its surrounding region, where the highest is 2.82HFU in the Tengchong, to the west of Baoshan. Dali and Jianchuan, situated in the north segment of the Red River fault area, also have

higher values 2.28HFU and 2.32HFU, respectively. The region to the east of the Western Yunnan has lower heat flow values. The high heat flow region is generally related to the tectonic activity (Institute of Geology, SSB and Seismological Bureau of Yunnan Province, China, 1990)..

Inversion of 3-D model

1. method

The simultaneous inversion approach is generally used to determine the velocity structure of the area beneath a network and a set of hypocentral parameters of local earthquakes. The problem can be expressed as solving the following linear equations:

$$r = A dx \quad (1)$$

where A is the matrix of hypocentral and medium partial derivatives, dx is the column vector of hypocentral and medium parameter perturbations, and r is the column vector of travel time residuals. The matrix A can be written in the following partitioned form:

$$A = \begin{bmatrix} H_1 & 0 & \dots & 0 \\ 0 & H_2 & \dots & 0 \\ \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & \dots & H_n \end{bmatrix} M \quad (2)$$

where H_i is the partial derivative matrix of the hypocentral parameter of the i 'th event, i.e. $(H_{jk})_i = (\partial T / \partial x_k) | (x_j, x_i')$, $i = 1, 2, \dots, n$. and x_j is the station position, x_i' is the hypocentral location, M is the partial derivative matrix of the medium. The residuals of an event are coupled to the residuals of another event by means of the medium matrix M only. For a single event, the corresponding equation is:

$$r_i = A_i dx_i \quad (3)$$

where r_i is the $(m \times 1)$ column vector, m is the observation number of the i 'th event, $A_i = [H_i, M_i]$. Pavlis and Booker (1980) showed that, when $m > 4$, equation (3) can be operated on to form a matrix equation which only contains the medium parameters. This processing is called parameter separation. It makes the calculation easy when the matrix contains a great number of arrival data.

Thurber's simultaneous inversion algorithm (Thurber, 1983) has been used to model the crust in this paper. In his algorithm, a 3-D grid approach is used, in which velocity varies continuously in all directions, with linear B-spline interpolation among the nodes. As for the ray path and travel time calculation, we use the pseudo-bending method of Um and Thurber (1987), which is basically an approximate but fairly accurate treatment of the exact bending method. Although there are some sophisticated improvements to the ray-tracing method recently developed, we did not use them due to the coarse resolution of the large station interval.

2. Data

The local first P arrival data were compiled from 26 permanent seismographic stations of KTSN, with 18 stations located inside the study area (Fig. 2) and 8 stations near the area. The basic data set contains the arrival data of 340 earthquakes collected by KTSN and 14 borehole shots from the DSS profiles, recorded by 160 temporary stations. The location error of the earthquakes in the data set is mostly less than 10km. Arrivals with distinct onsets recorded from shots were collected. In order to converge normally to the earthquake location, we set the following criteria for the data set: (1) the maximum gap of station orientation for an earthquake is less than 160°; (2) the minimum number of P travel time observations is 7; (3) the maximum residual of the travel time is 2.0s. The arrival times were mostly taken from the Observatory Report of KTSN, and larger residuals from some stations were checked on the seismograms. After the data selection, the number of earthquakes used for the inversion was 266 (Fig. 5). The total number of observations was 2681, where 2331 were for earthquakes, and 350 from the DSS blasts (Fig. 6).

3. Initial model

A grid model of Thurber (1983) is used in this study. The initial 3-D model is a laterally homogeneous 1-D model. The horizontal division into a 3-D grid model is shown in Fig. 2, where the grid extent is from 24.5° to 27°N in latitude and from 99° to 100°E in longitude, with intervals of 0.5°, respectively. The vertical grid is listed in Table 1 where the layer below 41km has a weak velocity gradient of 0.01km/s. The Moho discontinuity is simulated as a transition layer from depth 38km to 41km with a strong gradient. Although the topography of Moho along the profile varies considerably, the depth of the Moho beneath the 3-D grid model is limited to the extent of 41 ± 2 km. The 1-D initial model in Tab. 1 is an average of the models presented by the DSS profiles.

Ray tracing in the 1-D model shows that first arrivals beyond a distance of about 170km are Pn phase, which is clear on the seismograms of the area. The seismographic stations in this network have relatively large station spacing. In most cases, both \bar{P} and Pn of an earthquake are recorded as first arrivals at the stations in the network. In addition, Pn can be simulated as a diving wave below the Moho on the grid model, which also illuminates the lower crust to a degree. Therefore, we try to obtain a model of the entire crust in the area. About 50% of the arrival time data in the data set are Pn phase. In general, the travel time of Pn phase is insufficient for earthquake location, the accuracy of the earthquake location is limited.

Table 1 1-D initial model

<i>Depth (km)</i>	<i>P-velocity (km/s)</i>
-1.0	4.50
0.0	5.25
5.0	5.90
18.0	6.20
38.0	6.70
41.0	7.95

The arrival time data from DSS profiles have higher reliability than the data from earthquakes. Therefore, we set the weight (3.0) to the DSS data in the inversion. According to the resolution and standard error assessment in the result of inversion, the final model is basically reliable, although the resolution of the lower crust is lower than that of the upper-mid crust in the model. The resolution of the uppermost mantle is fair.

4. Final 3-D model

The number of rays that passed through the vicinity of a node is generally sufficient for the inversion. The number of rays for all of the 180 nodes is greater than 30. The final 3-D model after 10 iterations is shown in Fig. 7. The relevant resolution and standard error at each node are shown in Fig. 8 and 9 respectively. The first layer at depth -1km generally has very poor resolution. The resolution and standard error of the solution of nodes at a depth of 5km and 18km are higher and lower than those at a depth of 38km and 41km, respectively. In general, the reliability of the solution at the nodes on the boundary of the study is less than the central nodes. Although the lower crust is illuminated by the Pn ray, the ray segment with a higher angle and a shorter path penetrates lower crust. The standard error at the depth of 41km varies from 0.10 to 0.15.

The velocity structure in the area is complicated. The velocity anomaly distributions at different depths are quite different (Fig. 7). The anomaly at a depth of 5km are similar to the remanent Bouguer gravity anomaly. However, it is different from that at a depth of 18km. The seismically active zones in western Yunnan (DL, JC and YS areas in Fig. 7d) are generally related to a negative anomaly at a depth of 18km, while they are related to a positive anomaly at a depth of 5km. This demonstrates that the earthquakes occur in the upper-middle crust which has a positive velocity anomaly and a negative velocity anomaly zone underneath.

The velocity anomaly at a depth of 41km is obviously divided by some of the main faults in this area. The Red River fault is the boundary between the positive and negative velocity anomaly. The Lancanjiang fault is also an distinct boundary. However, another positive anomaly region to the northwest of DL in Fig. 8c is difficult to explain.

Based on the velocity anomalies at the nodes, Fig. 10 shows a cross section with relative velocity anomaly of the entire crust. The cross section is from the node of (25°N, 99°E) near BS to the node of (27°N, 101°E) near YS (Fig. 5) with a middle point at DL and trending NW. The image shows that there are negative anomaly zones in the mid-crust in the northwest and in the lower crust in the southwest, which are consistent with the DSS results. The Red River fault passes through the neighborhood of DL and is clearly seen as the boundary between two tectonic units, the Yangtze Platform and the Sanjiang Fold System. The reflection from the Moho is unusually energetic in the Western Yunnan area. However, on the record section of the BS shotpoint-NE on the DSS in-line profile, the reflection from the Moho is too weak to be recognized (Kan et al., 1986). Both the anomalous low velocity zone existing in lower crust and the obscure Moho discontinuity may be generated by the magma underplating.

Discussion

The 3-D velocity model of the crust beneath the Western Yunnan, China was obtained from the inversion. However, it is coarse due to the large station spacing, although the seismic activity is high level in this area. In order to improve the accuracy of location and rise the reliability of the final model, the unique way is to increase the number of stations and decrease the station interval in the study area.

Nevertheless, some significant insights are still obtained from the final model. The complicated velocity model may be related to the evolutionary history of the study area. This area is located at the junction of three major tectonic units, each having a different geological history. Based on the study of the rocks and their different geological histories on either side of the Red River fault, the fault is considered a main boundary of the tectonic units (Allen et al., 1984). However there is no clear evidence for a change in the velocity distribution across the fault on the DSS profiles (Kan et al., 1986). Images at a depth of 41km in this study show different velocity anomalies on either side of the fault. The reason for the inconsistent results may be due to sparse data from the Moho in the DSS profiles.

The lower mean velocity (6.2-6.3km/s) of the entire crust, and the negative velocity anomaly of the mid-crust in the area are consistent with the tectonically active area (Mooney and Brocher, 1987). This feature is similar to the North China Basin, another seismically active zone in China.

The focal depth of most earthquakes lies between 5 and 20km. The velocity anomaly distribution shows that the cluster of earthquakes is located above a negative anomaly zone and/or close to a large fault. The seismically active zones in the area are generally related to a negative anomaly at a depth of 18km in the model, and to a positive anomaly at a depth of 5km. This may imply that earthquakes occur in the upper-middle crust which has a positive velocity anomaly, and above a negative velocity anomaly zone which may play a role in the earthquake-generation.

In the region between BS and DL, the negative velocity anomaly in the lower crust is consistent with the weak energy reflection from the Moho at the BS shotpoint-NE and the high heat flow values may be related to the magmatism in the region of the Tibet-Yunnan Fold System.

Acknowledgments

This study is a part of the project of the China-U.S. Seismological Cooperation. The earthquake data and the DSS data in this study were collected respectively in the Kunming Telemetry Seismic Center, Seismological Bureau of Yunnan Province, and in the Institute of Geophysics, SSB of China, with assistance of W.L. Tong, Q.Z. Yan, Z.Y. Lin and R.J. Kan. The calculation in this study used the inversion program written by C.H. Thurber. The authors wish to express the sincere thanks to them.

ABSTRACT

More than 36,000 km of Deep Seismic Sounding (DSS) profiles have been collected in China since 1958. However, the results of these profiles are not well known in the West due to the language barrier. In this paper, we summarize the crustal structure of China with a new contour map of crustal thickness, nine representative crustal columns, and maps showing profile locations, average crustal velocity, and P_n velocity. The most remarkable aspect of the crustal structure of China is the well known 70 + km thickness of the crust of the Tibetan Plateau. The thick (45-70 km) crust of western China is separated from the thinner (30-45 km) crust of eastern China by the north-south trending seismic belt (105° E). The average crustal velocity of China ranges from 6.15 to 6.45 km/s, indicating a felsic-to-intermediate bulk crustal composition. Upper mantle (P_n) velocities are 8.0 \pm 0.2 km/s, equal to the global continental average. We interpret these results in terms of the most recent thermo-tectonic events that have modified the crust. In much of eastern China, Cenozoic crustal extension has produced a thin crust with a low average crustal velocity, similar to Western Europe and the Basin and Range Province, Western USA. In western China, Mesozoic and Cenozoic arc-continent and continent-continent collisions have led to crustal growth and thickening. Inferences on the process of crustal thickening are provided by the deep crustal velocity structure as determined by DSS profiles and other seismological studies. A high velocity (7.0 - 7.4 km/s) lower crustal layer has been reported in western China only beneath the southernmost Tibetan Plateau. We identify this high velocity layer as the cold lower crust of the subducting Indian plate. As the Indian crust is injected northward into the Tibetan lower crust, it heats and assimilates by partial melting, a process that results in a reduction in the seismic velocity of the lower crust in the central and northern Tibetan Plateau.

Introduction

The geology of China is highly diverse and records a history of crustal evolution from the Archean core of the Sino-Korean platform to active continent-continent collision in Tibet (Fig. 1). In addition, China is a country with a large population and high levels of seismic activity. Knowledge of the regional crustal structure is therefore important for the determination of epicentral locations, and for relating seismicity patterns to lateral variations in crustal properties.

Approximately 36,000 km of deep seismic sounding (DSS) profiles have been recorded by several institutions in continental China since 1958, primarily by the State Seismological Bureau (SSB) of China, the country's main DSS research group. In this paper, we begin with a brief description of the geologic and seismotectonic setting of China, and then summarize the main results of DSS investigations. While some of the results from these DSS profiles are known in the West, much information has not left China due to the language barrier. We provide a broad overview of the crustal structure of China rather than a detailed discussion of each profile.

Geology and Tectonics of China

Like many other continental regions, the geology of China consists of Precambrian platforms surrounded by accreted terranes and fold belts of various ages. These tectonic elements first assembled

in the Paleozoic era, but have been further deformed and rearranged in multiple episodes throughout the Mesozoic and Cenozoic. The following geologic summary is based on reviews by Zhang et al. (1984), Dewey et al. (1988), Windley (1995), Carroll et al. (1995), and Goodwin (1996).

There are three Precambrian platforms in China: the Sino-Korean platform, the Yangtze platform, and the Tarim basin (which, despite its common name in Western literature, is referred to as a platform in Chinese literature; Fig. 1). The Sino-Korean platform coalesced in the early Archean through Early Proterozoic; it was largely consolidated by 2.0 Ga. The Yangtze platform contains igneous and metamorphic rocks that range in age from late Archean through Late Proterozoic. This platform was consolidated and stabilized after the Yangtze orogeny (ca. 825 Ma.). The Tarim basin of NW China consists of a nucleus of Archean through Proterozoic age covered by thick Cenozoic sediments. The Tarim basin and Sino-Korean platform collided with the Siberian craton in the Early Paleozoic, creating an east-west arc of fold belts across northern China (Fig. 1) and forming the Paleo-Asian supercontinent. The Yangtze and Sino-Korean platforms, which had been separated by the Paleo-Tethys Ocean, collided in the early Mesozoic to form the Qinling fold system.

The South China fold system of SE China (Fig. 1) is a composite of late Proterozoic through Mesozoic orogens developed from three continental fragments now joined at two well-defined suture zones. The region was stabilized by the beginning of the Jurassic (Hsu et al., 1990).

South of the Tarim basin, the Kunlun fold system and the Tibetan Plateau (which may be subdivided into five fold systems that become younger to the south; Fig. 1) consist of a series of micro-continental fragments, collapsed ocean basins, accretionary metasedimentary rocks, and volcano-plutonic arcs that assembled at the southern margin of Eurasia after the breakup of Gondwana. The most recent major orogeny in southern Eurasia is the Himalayan collision (commencing ca. 45 Ma.), and has been marked by 2,000 km of convergence between India and Eurasia.

Crustal Structure of China

Profile Locations, Data Acquisition and Interpretation

The crustal structure of China has been well investigated with DSS profiles concentrated in regions of high population density and/or high levels of seismicity (Fig. 2). Table 1 provides a summary of 22 published profiles; in addition, we have used the results from 19 profiles that are not yet published (dotted lines on Fig. 2). Data quality, in terms of signal-to-noise ratio, is generally very good.

A variety of methods have been used to interpret the DSS data reported here. By far the most common method is the interpretation of seismic travel times and amplitudes using either one- or two-dimensional (1D and 2D) modeling methods (c.f. Mooney, 1989). In reversed DSS profiles, seismic velocities are directly measured, while depths of refraction (or reflection) horizons are successively calculated from the uppermost layer to the deepest measured horizon (usually the Moho). Thus, seismic velocity determinations generally have lower errors than depth determinations. For the seismic profile data compiled here, seismic velocities are accurate to within 3%, or about ± 0.2 km/s. All boundary depths (including the Moho) are accurate to within 10% of the depth.

Maps of Crustal Parameters

Crustal thickness is a parameter that is well determined by DSS profiles, since both refracted and reflected arrivals are usually observed from the Moho. However, the map of crustal thickness we present (Fig. 3) is the first complete contour map of the crustal thickness of China based primarily on DSS data. Previous maps have been largely based on surface wave, gravity, topography, and geoelectrical data (Compiling Group, 1986). The contour map clearly divides China into an eastern portion with a crustal thickness of 30-45 km, and a western portion with a thickness of 45-70 km. In western China, crustal thickness is positively correlated with

topography. The 70-km-thick crust beneath the Tibetan Plateau constitutes some of the thickest crust in the world (Allegre et al., 1984; Hirn et al., 1984 a, b; Teng, 1987; Teng et al., 1974, 1983), along with the central Andes of South America. The strong gradient in crustal thickness in central China (visible in gravity as well as seismic data) is coincident with the north-south trending seismic belt (105° E). In addition, the east-west trending fold belts of western China either end at or abruptly change direction when crossing this seismic belt (Fig. 1).

Worldwide, P_n velocities for continental mantle range from 7.6 km/s to about 8.4 km/s (higher values are occasionally reported; Christensen and Mooney, 1995). Low P_n velocities (7.6-7.8 km/s) are usually restricted to regions of thin (<35 km) crust with moderate to high heat flow, and high P_n velocities correlate with thicker crust (> 40 km) with low heat flow (i.e., stable continental interiors).

Figure 4 shows P_n velocities determined from refraction profiles in China. There is a weak tendency for northeast-southwest refraction profiles to show higher P-wave velocity values (8.1-8.2 km/s), and for northwest-southeast profiles to show lower values (7.7-8.0 km/s). This indicates possible seismic anisotropy in the uppermost mantle of about 4%.

Average crustal velocity, a parameter well determined from DSS data, is of interest because it is directly related to bulk crustal composition, assuming that the measured velocity has not been strongly reduced by anomalously high crustal temperatures or high pore pressure. A low average crustal velocity (6.0-6.3 km/s) is indicative of a dominantly felsic composition, and a higher average velocity (6.5-6.8 km/s) indicates a significantly more mafic crustal composition (Christensen and Mooney, 1995; Rudnick and Fountain, 1995). Figure 4 summarizes the average crustal velocity for the profiles in China from which we were able to make reliable calculations. Significantly, most values are less than or equal to the global average of 6.44 km/s (Christensen and Mooney, 1995). We interpret this to indicate a dominantly felsic to intermediate bulk crustal composition, whereas "typical" (i.e., platform and shield) crust has a significantly more mafic composition. This raises the question of why much of the crust of China is "atypical" in terms of its composition.

Crustal Evolution

Crustal velocity columns (Fig. 5) provide insights into the evolution of the crust of China. The five crustal columns for eastern China all indicate relatively thin (29-33 km) crust, close to the continental global average for extended crust (30.5 km), but significantly thinner than the global average of 39 km (Christensen and Mooney, 1995). This observation, along with geologic evidence, is consistent with Cenozoic crustal extension in eastern China (Hsu et al., 1990; Zhao and Windley, 1990). The low average crustal velocity (Fig. 4) and uppermost mantle velocity (7.8-8.2) are consistent with this inference, as are global tomographic models that indicate low shear-wave velocities in the upper mantle (i.e., thin lithosphere) of eastern China south of 42° N (Su et al., 1994; Zhang, 1996). Northeastern China (above 42° N) has no crustal refraction data, but global tomographic models (Ekström et al., 1997) provide evidence for a thick lithospheric root, and geologic evidence does not indicate significant Cenozoic crustal extension.

The crustal columns for western China (Fig. 5) show thick crust that is characteristic of young orogenic belts. Three of the four columns differ from the thick crust of shields in that they lack a high-velocity (7.0-7.6 km/s) lower crustal layer (Christensen and Mooney, 1995). These three crustal columns are best considered in light of recent seismological studies in western China that define crustal and upper mantle properties on both a regional scale (McNamara et al., 1994, 1995, 1996; Beckers et al., 1994; Zhu et al., 1995) and locally for the southern Tibetan Plateau (Fig. 1; Allegre et al., 1984; Hirn et al., 1984a,b; Zhao et al., 1993; Nelson et al., 1996; Makovsky et al., 1996a,b). These data are consistent with a model for the evolution of western China that is based on the concepts proposed by

Zhao and Morgan (1987) and Nelson et al. (1996). The key concept of this model is that the middle and lower crust of the Tibetan Plateau is a fluid-like layer, and the crust of India is injected into the Tibetan crust as an initially cold slab, but is heated and partially melted after moving 200 - 300 km northward. Thus, the crust of India is assimilated into the crust of Tibet, and the surface of the Plateau is raised by the increasing crustal volume. We interpret Column (a) (Fig. 5) to show the high-velocity (7.1 km/s) lower crust of the Indian shield prior to its heating and assimilation into the lower crust of Tibet. Such a high velocity lower crustal layer appears to be missing beneath the central and northern Plateau. Bordering the Plateau, the thick crust of Sichuan Province (column c) and Western Yunnan Province (column d) appears to reflect the eastward extrusion ("escape") of this crust from the Tibetan Plateau (Tapponnier et al., 1982).

In summary, the crustal structure of China closely reflects the most recent thermo-tectonic event that has modified the crust. The most recent processes that have dominated crustal evolution are continent-continent collision (western China) and crustal extension (eastern China). Despite the long history of crustal evolution, very little stable continental crust with "typical" seismic properties has been formed to date in China.

Acknowledgments

We are grateful to many people for sharing the information that is summarized in this paper. Zhang Xian-Kang, Zeng Rong-Sheng, Wang Chun-Yung, Wang You-Xue, and Yuan Xue-Chung provided data from China, and Katharine Favret and Regina Patzwahl provided helpful comments. Support from the USGS Earthquake Hazards Reduction Program and the Deep Continental Studies Program are gratefully acknowledged.

Figure Captions

Fig. 1

Tectonic sketch map of China (after Huang et al., 1980).
Nearly all geologic provinces have been surveyed with seismic refraction profiles (Fig. 2).

Fig. 2

Location map of the seismic refraction/wide angle reflection profiles in China (1958-1990).
The profile numbers correspond to Table 1.

Solid lines: profiles completed from 1958 to 1986

Dotted lines: profiles completed from 1987 to 1990; not yet published

Dashed lines: profile with sparse observational points

Fig. 3

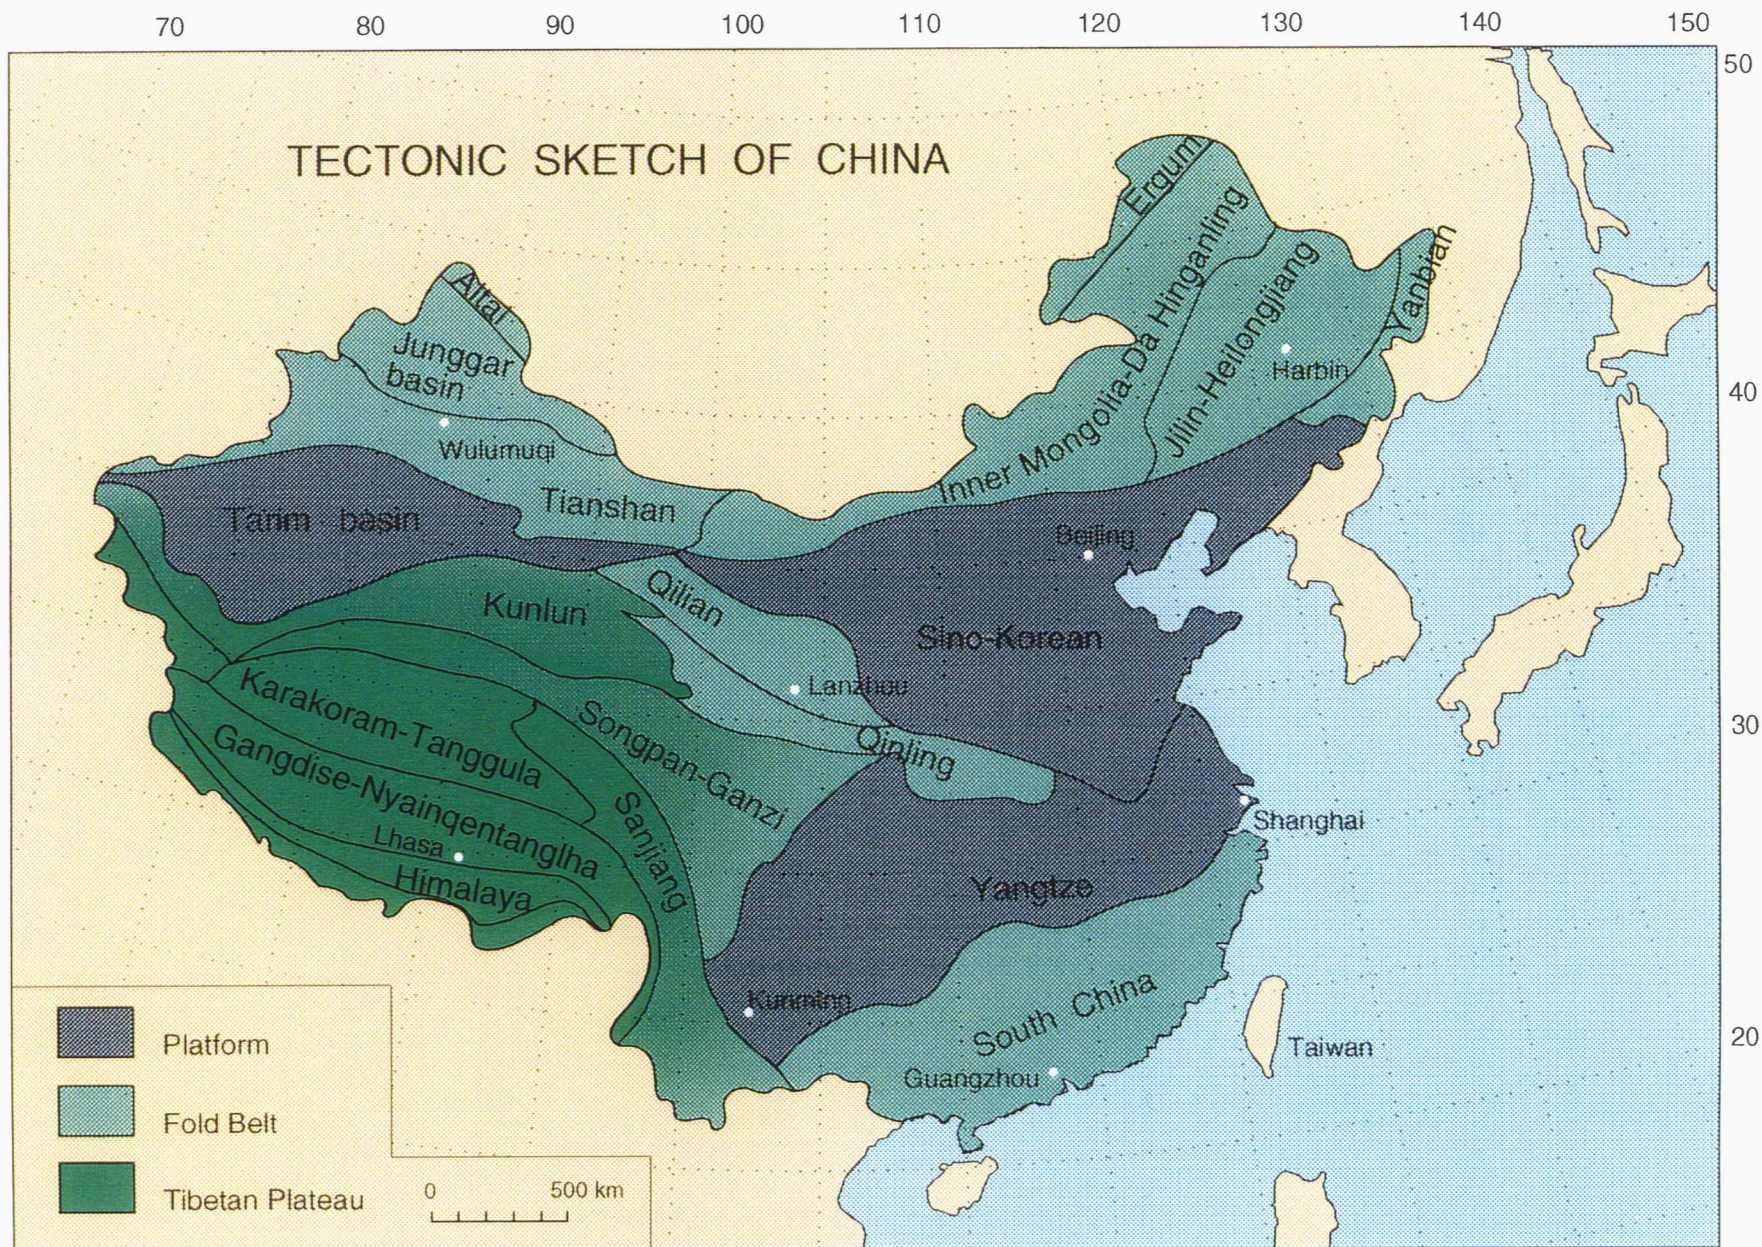

Crustal thickness obtained primarily from seismic refraction/ wide angle reflection experiments. Solid isolines represent more reliable results. Dashed lines were obtained by considering gravity data. The 45 km contour coincides with the western boundary of the Sino-Korean platform and the Yangtze platform, as well as with the north-south seismic belt (Fig. 2).

Fig. 4

Pn (upper mantle; in parenthesis) and average crustal velocities obtained from seismic refraction profiles in China. Pn velocities are well within the global average of 8.0 ± 0.2 km/s. Average crustal velocities range from 6.14-6.45 km/s, corresponding to a felsic to intermediate bulk crustal composition. Average crustal velocities greater than 6.45 km/s, which are commonly reported for the Precambrian of Russia, are not measured in China.

Fig. 5

Representative seismic velocity-depth functions for nine regions of China which can be divided into two parts by the north-south trending seismic belt (105°): western region (a-d) and eastern region (e-i). In the western region, the crustal thickness is greater than 45 km, while it is less than 35 km in the eastern region.

Dear Madame Wang,

Thank you for your fax message with news about the Sino-US Joint Workshop on Geodynamics and Seismic Hazards to be held in Shanghai July 15-18, 1998. I was very pleased to receive your message. I have already discussed your FAX with Prof. Francis Wu.

Your draft plan is excellent. I was pleased to read that Prof. Ma Zongjin of the Institute of Geology had agreed to join Pro. Chen as Co-Chairman. These two scientists are very distinguished, and are well known in America.

The list of five main topics is very suitable for our workshop. The suggested topics are likely to encourage interesting and stimulating presentations.

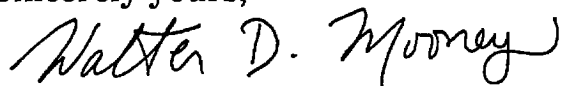

Your message included the names of about 15 Chinese participants, and I was pleased to see that many of the most important and creative scientific leaders were included there. We will try to

organize an American delegation that is well matched to this distinguished group of Chinese Earth Scientists.

Prof. Francis Wu and I have made a preliminary list of possible American participants. Our goal is to include people who are excellent scientists, and who are likely to propose cooperative work through the US National Science Foundation and the USGS. At present we have too many names on our list, and we need to discuss our ideas further in order to reduce the number to about 10-12 leading scientists. I hope that Dr. Leonard Johnson at the NSF will assist us in selecting these final names.

Thank you for your message. We are confident that a very important Workshop will result from our efforts.

Sincerely yours,

A handwritten signature in black ink that reads "Walter D. Mooney". The signature is written in a cursive, flowing style.

Re: Joint Workshop on Geodynamics and Seismic Hazard

March 2, 1998

Dear Dr. Walter D. Mooney:

According to the coordinators' meeting and our discussion in last November, a joint workshop on geodynamics and seismic hazard will be held in Shanghai this July, just before the Western Pacific Geophysical Meeting. Through the efforts of different departments and scientists of the Chinese side, a preliminary schedule for the meeting has been worked out. Attached, please find the draft plan. We would like to know if the time and topics are suitable for you and your colleagues. Please feel free to make comments and suggestions. Also, we'd like to know the name list of participants from the U.S. side at your earliest convenience.

I am looking forward to hearing from you soon.

With my best wishes.

Sincerely yours,

Wang Hongzhen, Director

MEMO

October 8, 1997

TO: Mr. He Yongnian
Deputy Director General, SSB

FROM: Walter D. Mooney, USGS Coordinator *Walter D. Mooney*
US-China Protocol on EQ Hazards Studies

RE: Official Invitation to Visit the United
States

This is an official invitation for an eight person delegation arranged by the State Seismological Bureau (SSB) to visit the United States in the period of around November 12-26, 1997. We understand that the delegates will visit scientific and governmental groups in several cities. The names of the eight delegates are:

1. Li Quianghua, Deputy Director, Office of General Administration, State Seismological Bureau
2. Guo Weiping, Deputy Division Director, Administration Office of the State Council
3. Zhou Chuanrong, Deputy Division Director, Ministry of Publicity

4. Luo Hongfu, Vice Secretary General, Gansu Provincial People's Government

5. Nur Bakry, Vice Secretary General, Xinjiang Uygur Autonomous Regional Government

6. Zhao Hongqi, Division Director, Administration Office, He Bei Provincial People's Government

7. Tan Xianfeng, Division Director, Office of General Administration, State Seismological Bureau

8. Ms. Li Jing, Deputy Division Director, Center for Analysis and Prediction

Terms of the Invitation: The US Geological Survey will make arrangements for all meetings with Federal, State and private organizations. A professional travel agency will handle all travel arrangements, and all expenses associated with this trip will be paid by the SSB

September 20, 1997

Dear Mr. Walter,

You must be back home again after the long flight from Beijing to San Francisco. I was very pleased to co-work with you in this year's Coordinators' meeting, and we had spent very busy but very fruitful days. In addition to the review of the ongoing projects, we also added some new projects which will provide more room for the scientists of both countries to play in the earthquake studies. We really enjoyed the down-to-earth spirit in the two days' meeting.

As we discussed on the afternoon of September 16, 1997 at Xiyuan Hotel, the State Seismological Bureau will send an education delegation to visit the United States for a period of two weeks. The proposed visiting period will be from November 18 to December 1, 1997. The name list of the delegation comes as follows:

1. Li Qianghua, Deputy Director, Office of General Administration,
State Seismological Bureau
2. Guo Weiping, Deputy Division Director, Administration Office of the State Council
3. Zhou Chuanrong, Deputy Division Director, Ministry of Publicity
4. Luo Hongfu, Vice Secretary General, Gansu Provincial People's Government
5. Nur Bakry, Vice Secretary General, Xinjiang Uygur Autonomous Region Government
6. Zhao Hongqi, Division Director, Administration Office,
He Bei Provincial People's Government
7. Tan Xianfeng, Division Director, Office of General Administration,
State Seismological Bureau
8. Ms. Li Jing, Deputy Division Director, Center for Analysis and Prediction,

Please remember me to Mehmet Celebi.

Yours Sincerely,

A handwritten signature in black ink, appearing to be '黄建发' (Huang Jianfa), written in a cursive style.

Huang Jianfa, Division Director

AGREEMENT-IN-PRINCIPLE

between the

STATE SEISMOLOGICAL BUREAU, PEOPLE'S REPUBLIC OF CHINA

and the

UNITED STATES GEOLOGICAL SURVEY

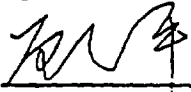

under Annex I of the Earthquake Studies Protocol

for

UPGRADES TO THE CHINA DIGITAL SEISMOGRAPH NETWORK

27 March 1990

Signed:

Gu Ping, PRC Side
Chief, Department of International
Cooperation, State Seismological Bureau

Date: May 8 1990

Signed:

Robert L. Wesson, USA Side
Chief, Office of Earthquakes, Volcanoes,
and Engineering, USGS

Date: March 27 1990

I. INTRODUCTION

The CDSN has been in operation since 1986, and has been producing high quality digital data for research seismologists world wide since early 1987. The CDSN data are made available to the research community through the CDSN Data Management Center (DMC) in Beijing, the USGS Albuquerque Seismological Laboratory (ASL), and the USGS National Earthquake Information Center (NEIC) in Golden, Colorado. These data are distributed by the CDSN DMC in the form of Network Day Tapes, by ASL as global network day tapes or volumes written in SEED (Standard for the Exchange of Earthquake Data) Format, and by NEIC in the form of CD ROM optical disks containing event data. The SEED volumes produced by ASL take the place of the Network Day Tapes produced previously by ASL. SEED volumes (presently tapes) are written in a standard format agreed upon by a significant portion of the international seismological community. Research seismologists are finding the inclusion of the CDSN data in the published data volumes to be a valuable asset in their studies. For example, the recent (Nov. 1988) large earthquake in Yunnan province can be studied in much greater detail because of the availability of CDSN digital data.

However, this particular earthquake pointed to the need for even greater dynamic range than is available in the present CDSN system. There was evidence of clipping on at least some channels at each of the five stations from which ASL receives data on a regular basis. The lowest gain channels are the broadband channels, and these did not show evidence of clipping except at Kunming. Installation of IRIS/GSN (also known as IRIS-2) equipment at the stations would allow the recording of broadband (BB) data at five times lower sensitivity than in the CDSN, so that large earthquakes would be even more likely to be recorded without clipping. Also the BB data would be recorded *continuously* instead of being triggered. The IRIS-2 data loggers may also be equipped with optional very short period (VSP) and low gain (LG) sensors to allow the recording of high frequency (up to 50 Hz) and high amplitude (up to 2g) waveforms of local and regional interest.

The desired capabilities for a Global Seismographic Network (GSN) of digital seismographic stations were defined as a result of the IRIS initiative. In 1984, the Incorporated Research Institutions for Seismology (IRIS) prepared a Science Plan for a New Global Seismographic Network (GSN). This plan was submitted to the US National Science Foundation (NSF) and resulted in a cooperative program between IRIS, NSF, and the USGS, to develop and install a modern digital broadband seismograph network of 50 to 100 stations distributed evenly around the globe. Based on the Science Plan's requirements, "The *Design Goals For A New Global Seismographic Network*," dated March 13, 1985, and a "5-Year *Siting Plan* IRIS Contribution to the Global

Digital Seismographic Network," dated March 28, 1986, were prepared. These two documents state in detail the technical specifications and the proposed station locations for the GSN stations.

The *Siting Plan* depends on the CDSN stations for seismographic coverage of China, as an integral part of the GSN. However, the CDSN stations do not presently meet all of the IRIS technical specifications in the *Design Goals*. In order for the CDSN to become a fully participating partner in the GSN program, it will be necessary to upgrade the CDSN stations and the DMC equipment to meet IRIS standards. These standards include:

1. **BANDWIDTH:** Sufficient bandwidth to adequately record the entire spectrum of seismic signals that propagate over distances that are large compared with the station separation, on the order of 20 degrees for a 100 station network. Broadband data should be recorded continuously at 20 samples per second, with higher frequency channels recorded on an event basis.
2. **RESOLUTION AND FULL-SCALE:** Over the specified bandwidth, the system should be capable of resolving signals at the level of minimum ambient ground noise and of recording signals from the largest expected teleseismic event. Neither the full scale clipping nor the system noise should obscure any signal of interest.
3. **LINEARITY:** The system output should be a linear time-invariant function of the ground motion. Further, the linearity should be such that signals near the ground noise minimum can be resolved in the presence of ground noise at other frequencies near the expected ground noise maximum.

In addition to these design goals, the GSN systems also have the ability to transmit any or all of the acquired data via a serial port to a host computer or central receiving station. There is also a dial-up port that may be connected to a telephone line or modem so that buffered data may be retrieved by calling the station processor from another computer. Up to six channels of LP or SP analog outputs are available for use in producing conventional analog seismograms on drum recorders.

The recording systems proposed for upgrading the CDSN over the next two to three years will meet all of the design goals for the GSN. In addition, the new DMC equipment proposed will be able to read tape cartridges from the upgraded stations and compile SEED network volumes from them and from existing CDSN tape cartridges.

In preparation for installation of IRIS-2 seismic data systems in China under this Agreement, the USGS and the SSB agree to cooperate in the early installation of Sun seismic data systems at four CDSN stations, and to telemeter

seismic data from these stations to the DMC in Beijing and to ASL. ASL will transmit event parameter data to the DMC in Beijing over the reverse link. The Sun seismic data systems at each station will operate for about one year or until an IRIS-2 data system is installed at that station. At that time, the Sun system may be attached to the IRIS-2 system as a work station, it may be moved as a complete system to another station, or it may be left in place and continue to be used as before.

The USGS will let a contract for the installation work and the training. The USGS field engineer in China and the SSB will assist the USGS and its contractor in installation of the Sun seismic data systems and telemetry links.

II. PURPOSE

The purpose of this Agreement-In-Principle is to list the steps necessary for upgrading the present China Digital Seismograph Network (CDSN) to be compatible with IRIS/GSN standards, to install Sun systems at four stations, and to assign the responsibilities and costs for each item to the PRC side or the USA side. This Agreement-In-Principle is understood by both sides to be within the original terms and conditions of Annex I to the Earthquake Studies Protocol, signed in 1980 by the State Seismological Bureau (SSB), the U. S. Geological Survey (USGS), and the U. S. National Science Foundation (NSF). It will result in an upgraded and expanded seismograph network in China, consisting of 10 IRIS/GSN-type stations, four stations with Sun systems and work stations, an upgraded Data Management Center (DMC), and an upgraded Network Maintenance Center or Depot (NMC). It will also result in data being telemetered by satellite from some stations to the DMC and from the DMC to the USA, and in earthquake parameter data being telemetered from ASL to the DMC in Beijing.

As with all cooperative activities under the USGS Protocol on Earthquake Studies, this activity is subject to the availability of funds.

III. USA SIDE RESPONSIBILITIES

A. Install Sun Seismic Data Systems.

1. At four CDSN stations, install a Sun seismic data system, including three short period seismometers, three broad band seismometers, digitizing system, digital recorder, work station, and Uninterruptible Power System (UPS). This equipment will be installed in addition to the current CDSN data system and seismometers.
2. The four stations will be Baijatan (BJI - near Beijing), Lanzhou (LZH), Hailar (HIA), and Urumqi (WMQ).

B. Upgrade Stations To IRIS/GSN Standards.

1. Upgrade five CDSN stations by replacing the present CDSN data logger and seismometer system with IRIS-2 data logger, VBB seismometer system, and possibly very short period (VSP) and/or low gain (LG) seismometer systems (optional).
2. The five stations will be:
Kunming (KMI), Mudanjiang (MDJ), Enshi (ENH), Qiongzong (QIZ), and Sheshan (SSE).
3. Upgrade the remaining four stations of the CDSN network, plus a new site at Lhasa, by replacing the present CDSN data logger and seismometer system with IRIS-2 data logger, VBB seismometer system, and possibly very short period (VSP) and/or low gain (LG) seismometer systems (optional).
4. The four stations in addition to the station at Lhasa will be:
BJI, LZH, HIA, and WMQ.
5. This will result in a total of 10 CDSN stations that fully meet IRIS/GSN standards.

C. Telemeter Data To Beijing And ASL.

1. Telemeter Sun System Data To Beijing And ASL:

Telemeter basically continuous VBB, LP, and SP data from the Sun systems at stations BJI, LZH, HIA, and WMQ to the DMC in Beijing and to ASL. The USGS and its contractor will work through the SSB with the China Broadcast Satellite Corporation (CBSC) in establishing two-way satellite links from each station to the DMC.

This responsibility includes the purchase and installation of VSAT electronics and antennas, satellite link lease costs, and installation of a land link or other surface link (such as a microwave link) from the CBSC Hub (Central Earth Station) to the DMC. It also includes the responsibility for any necessary land link for connecting the DMC to the out-going satellite link to the USA.

The land link or other surface link from the CBSC Hub to the DMC will be installed with a minimum capacity of 112,000 bits per second to allow for future expansion by SSB.

2. Telemeter IRIS-2 System Data To Beijing And ASL:

For stations BJI, LZH, HIA, KMI, WMQ, and Lhasa (after upgraded to IRIS-2), telemeter basically continuous very broad band (VBB) and LP data, very short period (VSP) events, and low gain (LG) events from the IRIS-2 systems to the DMC in Beijing, and from the DMC to the Albuquerque Seismological Laboratory (ASL).

3. Telemeter event parameter data from the National Earthquake Information Center (NEIC) in Golden, Colorado, through ASL to the DMC in Beijing on the reverse satellite link. Telemeter parameters for all events detected in China greater than Richter magnitude 5 and for all other events in the world greater than magnitude 6, if available. Also telemeter to the DMC event waveforms, if available, upon special request from the DMC.

D. Upgrade Data Management Center.

1. Upgrade the computer equipment of the DMC to Digital Equipment Corporation (DEC) Microvax III computer(s), capable of writing SEED network volumes from IRIS-2 station tape cartridges and from current-type CDSN station tape cartridges.
2. Install in the DMC one or two Sun computers to be used as telecommunications computers to receive data from Sun systems and/or IRIS-2 systems at the stations and transmit data to ASL, to receive event parameter data from ASL, and to function as a work station. Connect the Sun computer(s) to the DEC computer(s) via DECNET.
3. Provide and install one IBM PC compatible computer in the DMC and connect it to the DEC computer(s) via DECNET.
4. Insure that the DMC will be capable of producing copies of station tapes, SEED network volumes, and possibly other data sets, on a variety of media that are convenient for data users. These media will include IBM PC floppy disks, station-type cartridges (150 Mbytes), Exabyte cartridges (1.5 Gbytes), and possibly 9-track tapes. If Exabyte cartridge drives are not exportable to China, a substitute high-capacity medium and drive will be provided.

E. Training.

1. Sun System Training For NMC And DMC People:

Sun system training in the USA will be provided for two NMC and two DMC technical English-speaking people who can prove equal to

this task, for two to three weeks.

2. IRIS-2 System Training For NMC And DMC People:

IRIS-2 system training for NMC and DMC people will be provided in a single training period in the USA for a total of 25 man-weeks (for example, 5 PRC people for 5 weeks). SSB agrees to send good technical people who can speak and understand English reasonably well. This training will take place just before the first station upgrades begin. Additional training will be provided in Beijing after the upgrades begin.

3. Station Operator Training:

Sun system training for station operators will be provided in China at the time of Sun system installation, either in Beijing or at the station site, at SSB's preference.

IRIS-2 system training for station operators will be provided in China at the time of IRIS-2 system installation, either in Beijing or at the station site, at SSB's preference.

F. Upgrade The Network Maintenance Center, Provide Spare Parts.

1. NMC Equipment And Parts For The Sun Systems:

Stock the NMC with spare parts and equipment for station systems and DMC telecommunications computer at a level sufficient to keep the Sun systems operating at a high percentage of up-time, and maintain that level of stock for the duration of the Sun system experiment.

2. NMC Equipment And Parts For The IRIS-2 Systems:

Provide one complete IRIS-2 station data acquisition system and install in the NMC, to be used for depot maintenance and check-out of station spare parts.

3. Stock the NMC with spare parts for IRIS-2 station systems at a level sufficient to keep the entire network operating at a high percentage of up-time, and maintain that level of stock for the duration of the cooperative agreement between SSB and USGS for operating the CDSN IRIS-2 network.

4. Upgrade and augment NMC test equipment as necessary for proper support and maintenance of the IRIS-2 data acquisition systems.

5. Provide one IBM PC compatible computer for the NMC, to be used as a diagnostic tool for the IRIS-2 station systems and for use in inventorying NMC spare parts.

G. Equipment For One Additional CDSN Station.

1. Ship one current-type CDSN system, including data acquisition system and UPS, to China for installation at Lhasa.
2. Provide technical assistance, as necessary, during installation of this equipment at Lhasa.

H. Network Support.

1. Sun Network Support:

Provide support for the Sun station systems and the Sun telecommunications computer. Provide field assistance in China as necessary to support the installation, operation, and maintenance of the Sun network. Provide operating supplies that are not available in China.

2. IRIS-2 Network And CDSN Support:

Continue to provide support for the current-type CDSN stations and IRIS-2 upgraded CDSN stations at BJI, WMQ, LZH, HIA, KMI, MDJ, ENH, QIZ, and SSE. Provide support for the current-type CDSN equipment at Lhasa, when installed. Provide support for IRIS-2 equipment at Lhasa, when installed. Continue to provide support for the NMC and the DMC in Beijing. Provide field assistance in China as necessary to support the continuing operation and maintenance of the CDSN. Provide operating supplies that are not available in China.

3. DMC Maintenance:

Provide maintenance of DMC equipment as much as possible by maintenance contracts.

The new system to be installed in Lhasa will be a standard format system in the same available.

The new system will ~~be installed~~ ^{be installed} in Lhasa. The PRC will be responsible for the installation and maintenance of the system. The system will be used for the collection and processing of seismic data. The system will be used for the collection and processing of seismic data. The system will be used for the collection and processing of seismic data.

IV. PRC SIDE RESPONSIBILITIES

A. Site Preparations For Sun Systems.

1. Perform any minor site upgrades and improvements at the four CDSN stations (BJI, LZH, HIA, and WMQ) as may be necessary for installation of the Sun systems. Also perform any necessary improvements of DMC and NMC facilities, such as additional space and better environmental controls, for installation of the Sun telecommunications computer.
2. Perform satellite signal strength tests and RF noise tests at stations BJI, LZH, HIA, and WMQ.
3. Cooperate with US technical personnel in checkout, installation, and acceptance testing of new equipment.
4. Provide all transportation of equipment in China.
5. Continue to provide daily management of the 9-station network, including the Sun systems at BJI, LZH, HIA, and WMQ. Continue to provide daily management of the DMC and the NMC, including the Sun system at the DMC.
6. Insure that seismic data are telemetered from the Sun systems at the four stations BJI, LZH, HIA, and WMQ to the DMC in Beijing, and from the DMC to ASL. Provide copies of Sun system station tapes for time periods during which telemetered data from these four stations are missing due to technical problems with the telemetry links.
7. Take whatever steps are necessary to insure that power is available to the DMC equipment 24 hours each day.

B. Site Preparations For CDSN System At Lhasa:

Prepare one new CDSN site at Lhasa for installation of current-type CDSN station equipment. This includes capital construction, seismometer vault or tunnel construction, and line power supply improvements, but not UPS.

C. Site Preparations For IRIS-2 Systems.

1. Perform necessary site upgrades and improvements at the nine existing CDSN stations to prepare for installation of IRIS-2 systems, such as improved line power, seismic noise surveys, and construction of improved seismometer vaults or tunnels. Also perform necessary improvements of DMC and NMC facilities, such as additional space and better environmental controls.
2. At stations KMI and Lhasa, perform satellite signal strength tests and RF noise tests in preparation for satellite telemetry of IRIS-2 data from those sites.

- D. Cooperate with US technical personnel in checkout, installation, and acceptance testing of new equipment.
- E. Provide all transportation of equipment in China.
- F. Provide daily management of the 10-station network, the DMC, and the NMC.
- G. Insure that data are telemetered from the IRIS-2 systems at the six stations BJI, LZH, HIA, KMI, WMQ, and Lhasa (after upgrade), to the DMC in Beijing, and from the DMC to ASL. ~~Provide copies of IRIS-2 station tape cartridges for time periods during which telemetered data from these six stations are missing due to technical problems with the telemetry links.~~
- H. Install the spare IRIS-2 station UPS in the NMC.
- I. Take whatever steps are necessary to insure that power is available to the DMC equipment 24 hours each day.
- J. If SSB wishes to telemeter data from the IRIS-2 systems at stations MDJ, ENH, QIZ, and SSE, such telemetry will be at the cost of the SSB. Any excess capacity available in the installed surface link from the CBSC Hub to the DMC may be used by SSB at no additional cost.

G. Insure that data are telemetered from the IRIS-2 systems at the six stations BJI, LZH, HIA, KMI, WMQ, and Lhasa (after upgrade), to the DMC in Beijing, and from the DMC to ASL. Provide copies of IRIS-2 station tape cartridges for time periods during which telemetered data from these six stations are missing due to technical problems with the telemetry links.

Insure that data are telemetered from the IRIS-2 systems at the six stations BJI, LZH, HIA, KMI, WMQ, and Lhasa (after upgrade), to the DMC in Beijing, and from the DMC to ASL.

Provide copies of IRIS-2 station tape cartridges for time periods during which telemetered data from these six stations are missing due to technical problems with the telemetry links.

Insure that data are telemetered from the IRIS-2 systems at the six stations BJI, LZH, HIA, KMI, WMQ, and Lhasa (after upgrade), to the DMC in Beijing, and from the DMC to ASL.

V. PROPOSED SCHEDULE

A. In 1990:

Install Sun systems alongside the current CDSN systems at BJI, LZH, HIA, and WMQ. Also install Sun telecommunications computer at the DMC, telemetry links from these four stations to the DMC, and a telemetry link from the DMC to ASL.

B. In 1990 and 1991:

Upgrade stations KMI, MDJ, ENH, QIZ, and SSE with IRIS-2 systems.

C. Beginning in 1990:

Upgrade the NMC to handle Sun systems and IRIS-2 systems. Upgrade the DMC to handle data from Sun systems and IRIS-2 systems, and to produce SEED network volumes.

D. In 1991 and 1992:

Upgrade stations BJI, LZH, HIA, WMQ, and Lhasa with IRIS-2 systems.

中华人民共和国国家地震局和美利坚
合众国地质调查局就列入地震研究
议定书附件一中关于改进中国
数字化地震台网的原则协议

签 字:

签 字:

国家地震局

美国地质调查局

日期 1990. 6. 5.

日期 7/7/90

一. 前言

1986年后,中国数字化地震台网(CDSN)已投入运行.从1987年初起已取得为世界地震学家所使用的高质量数字化资料.研究团体可通过中国北京CDSN的数据管理中心(DMC),美国地质调查局的阿尔布开克地震实验室(ASL)和科罗拉多州戈尔登的美国地质调查局国家地震情报中心(NEIC)得到该台网的资料.这些资料可由该台网的数据管理中心以网日带的形式,阿尔布开克地震实验室以全球网日带或以地震数据交换的标准(SEED)格式编成的文件形式以及美国国家地震情报中心编成的含事件数据的CD-ROM光盘形式进行散发.阿尔布开克地震实验室编成的标准文件已取代早先的网日带.标准文件(目前的磁带)已采用得到大多数国际地震学术团体认可的标准格式写成.地震学家们正在发现,在已发行的资料中,该台网数据对他们的研究有很大的帮助.譬如,对最近(1988年11月)云南省的大地震,基于该台网数字化数据的可用性,可进行更为深入的研究.

然而,这一特有的地震还表明需要有比目前现有该台网系统更大的动态范围.在常规的基础上,阿尔布开克地震实验室得到5个台的资料,每一个台至少有若干道数据已明显限幅.最低增益信道是宽频带信道,除昆明台外,其它台没有明显限幅.如在台站上安装IRIS/GSN(也称IRIS-2)设备,可记录到比该台网记录灵敏度低五倍的宽频带(BB)数据,而不会限幅.再者,宽频数据由连续记录代替原来的触发记录. IRIS-2数据记录器也可配备附加的甚短周期(VSP)和低增益(LG)传感器以记录感兴趣的地方震和区域地震的

高频分量(高至 15Hz)和大振幅波形(直到 2g)。

全球地震台网(GSN)的数字地震台网所期望的性能是通过 IRIS 的计划而确定的。1984 年,地震学联合研究集团(IRIS)拟定了一份关于新全球地震台网(GSN)的科学计划。该计划提交给美国科学基金会(NSF)进行审议,结果产生了该集团、美国科学基金会、和美国地质调查局之间一项关于研制和安装一个全球均匀分布、由 50 至 100 个台站所组成的现代化数字宽频带地震台网的合作计划。基于该科学计划的需要,于 1985 年 3 月 13 日制定了“关于新全球地震台网的设计目标”,并于 1986 年 3 月 28 日制定了“关于全球数字地震台网 IRIS 布局的五年场地计划”。这两份文件详细规定了台站的技术指标和建议的场地位置。

作为全球台网整体的一部分,中国数字化地震台网台站的场地计划取决于对中国的地震覆盖。但是,现有台网台站并非全部满足 IRIS 设计目标规定的技术指标。为了使该台网成为全球台网计划的合乎规范的参与伙伴,必须对台网台站和数据管理中心设备进行改进以适应 IRIS 标准。这些标准包括:

1. 频带宽度:足够的频带宽度可记录传播距离比台站间距大的地震信号的全部频谱,对于 100 个台的台网,台站间距约为 20 度。宽频带数据每秒采样 20 次,连续记录,而高频信道则以事件触发为基础。

2. 分辨率和满量程:对于规定的带宽,系统可以从最低环境地噪声水平中分辨出信号,并记录所期望的最大远震信号。既不会满量程限幅又不会使系统噪声掩盖任何感兴趣的信号。

3. 线性度:系统输出是线性时不变函数。此外,其线性度应在有

地动噪声的情况下,接近最小地动噪声的信号在接近所期望的地动噪声最大值的其它频带上可分辨出来。

除上述设计目标外,全球台网还有通过一系列转接站向一台主计算机或中心接受站传输任一或全部已得到的数据的能力。有一种拨号接口可连接到电话线或调制解调器上,以使用一台计算机访问基地信息处理机取回已缓存的数据。可得到多达 6 道长周期或短周期的模拟输出可用于在纸鼓记录器产生传统的模拟地震图。

为改进中国数字化地震台网,在今后二三年时间内安装所建议的记录系统将满足全球台网的全部设计目标。此外,所建议的新的数据管理中心设备将具有阅读由改进台站得到的匣式带和编辑 SEED 台网文件的能力,也具有阅读现有台网匣式带和编辑 SEED 文件的能力。

按此协议,为准备在中国安装 IRIS-2 型地震数据系统,美国地质调查局(USGS)和中国国家地震局(SSB)同意在四个台站上先期安装 SUN 地震数据系统,并将数据由这些台站遥测到北京数据管理中心(DMC),并从该中心传输到美国阿尔布开克地震实验室(ASL),该实验室将在反向链路上把事件参数数据传输到北京。每个台站的 SUN 地震数据系统将运行大约一年或直到该台站安装一套 IRIS-2 数据系统时为止。那时,这个 SUN 系统可作为一个工作站并入 IRIS-2 系统,或者作为一套完整的系统移到另一台站,或者继续留在原地使用。

美国地质调查局将签订一项关于安装和培训合同。由美国地质局派往中国的现场工程师和国家地震局将协助美方及其合同人员安装 SUN 地震数据系统和遥测链路。

二.目的

该原则协议的目的是列出改进现有中国数字化地震台网以适应 IRIS / GSN 标准所需要采取的步骤,在四个台站安装 SUN 系统,以及规定中方和美方的职责和费用.双方一致同意该原则协议由中国国家地震局,美国地质调查局,美国科学基金会于 1980 年签署的地震研究议定书附件一中原有的条款和规定.根据此协议,将对 中国地震台网进行改进和扩展,即由 10 个 IRIS / GSN 类型的台站,四个具有 SUN 系统和工作站的台站,一个改进的数据管理中心(DMC),一个改进的台网维护中心或检修站(NMC)所组成.同时,一些台站的数据将依此通过卫星传输到数据管理中心,并从该中心传输到美国以及把地震参数数据从美国传送到北京.

象所有的美国地调局执行地震研究议定书中的合作活动一样,本项活动也受经费的制约.

三.美方职责

A.安装 SUN 地震数据系统

1.在其中四个台站上,各安装一套 SUN 地震数据系统.包括三个短周期地震计,三个宽频带地震计,模数转换系统,数字记录器,工作站和不间断电源.

2.四个台站确定为白家瞳(BJI-北京附近),兰州(LZH),海拉尔(HIA)和乌鲁木齐(WMQ).

B.改进台站以达到 IRIS / GSN 标准

1.用 IRIS-2 型数据记录器,甚宽频地震计系统,或甚短周期

(VSP)和(或)低增益(LG)地震计系统(任选)取代现有其它五个台站的数据记录器和地震计系统.

2.这五个台站是:昆明(KMI),牡丹江(MDJ),恩施(ENH),琼中(QIZ),和余山(SSE).

3.通过用 IRIS-2 型数据记录器,甚宽频地震计系统,或甚短周期(VSP)和(或)低增益(LG)地震计系统(任选)取代目前台网的数据记录器和地震计系统以改进其余四个台站,并新增设一个拉萨台站.

4.除拉萨台外,其余四个台是:北京,兰州,海拉尔和乌鲁木齐.

5.完全符合 IRIS / GSN 标准的台站总数为十个.

C.传输数据到北京和美国:

1.遥测传输 SUN 系统数据到北京和美国:

在基本连续的基础上,把甚宽频,长周期和短周期数据从安装 SUN 系统的四个台站传送到北京的数据管理中心(DMC)和阿尔布开克地震实验室(ASL). 美国地调局和它的合同人员将通过国家地震局与中国广播卫星公司(CBSC)为每个台站与北京间,北京与美国间建立双向卫星链路. 该款职责包括购置和安装 VSAT 设备和天线,卫星通道租金和由中心地面站(CES)到中心安装一条地面链路(例如:微波链路).还包括提供由中心到卫星的引接和传输到美国所需的任何必要的链路.从卫星公司插孔到数据中心的在地面引接链路或地表链路应不少于 112Kb/s 的容量,以便于地震局的扩充使用.

2.遥测传输 IRIS-2 系统数据到北京和美国:

在基本连续的基础上,将北京,兰州,海拉尔,昆明,乌鲁木齐和拉萨(完成改进到 IRIS-2 后)的甚宽频带数据,长周期数据,甚短周期

事件和低增益 (LG) 事件传输到北京, 并从北京传输到美国。

3. 由科罗拉多州戈尔登的美国国家地震情报中心 (NEIC) 向中国北京通过反向卫星链路传输事件参数数据。关于传输所有检测到的事件参数, 是指已得到的发生在中国的大于里氏震级五级的和发生在中国以外的大于里氏震级六级的事件参数。如果北京特殊需要, 也将向北京传输已得到的事件波形。

D. 改善数据管理中心

1. 用 DEC 公司的 MICRO VAXIII 计算机改善中心的计算机设备, 该计算机具有将 IRIS-2 台站匣带和现有台网台站匣带的数据编写为 SEED 文件的能力。

2. 在中心安装一或二台 SUN 计算机, 以用作远程通讯计算机, 接受台站数据和传输数据到美国。通过 DECNET 将 SUN 计算机与 DEC 计算机联机。

3. 为中心提供和安装一台 IBM PC 可兼容的计算机, 通过 DECNET 使它与 DEC 计算机联机。

4. 为方便数据用户将保证中心拥有多种媒质以生产台站磁带拷贝, SEED 台网文件和可能的其它类数据集。这些媒质包括: IBM-PC 机软盘, 台站型匣带 (150MB), 高容量匣带 (1.5GB), 可能还有 9 轨磁带。如果高容量匣带驱动器不准向中国出口, 将提供代用的高容量媒质和驱动器。

E. 培训

1. 对台网两个中心的人员进行 SUN 系统培训。

每中心有两位能胜任该份工作, 会讲英语的技术人员赴美培训 2 到 3 周。

2.对台网两个中心人员进行 IRIS-2 系统培训.

在美国将安排一次对 NMC 和 DMC 人员进行 IRIS-2 系统的培训,总数为 25 人周(例如,5 个中方人员 5 周).国家地震局派具有英语听说能力和有经验的技术人员赴美.培训将安排在第一个台站改进开始之前.在改进开始后,将在北京提供附加培训.

3.台站操作员培训.

对台站操作员的 SUN 系统培训将在安装 SUN 系统时在中国进行,具体安排由地震局确定.

对台站操作员的 IRIS-2 系统培训将在安装 IRIS-2 系统时在中国进行,具体安排由地震局确定.

F.改进台网维修中心(NMC),提供备件

1.维修中心用于 SUN 系统的设备和部件.

在维修中心存贮的用于台站系统和管理中心远程通信计算机的备件和设备必须保证 SUN 系统能以高百分率运行及满足试验期间维修所需的贮备水平. 2.维修中心用于 IRIS-2 系统的设备和部件.

为维修中心提供一套完整的 IRIS-2 型台站数据采集设备,以用于台站备件的检修和测试.

3.在台网维修中心贮备足够的台站系统备件,以保持整个台网在一个高百分率下正常运转,并在国家地震局与美国地调局执行台网合作协议期间保持这一贮备水平.

4.改善和增加维修中心的必需测试设备,以进行常规支持和用于 IRIS-2 数据采集系统的检修.

5.为维修中心提供一台 IBM-PC 兼容式计算机,作为 IRIS-2

台站系统的一种故障诊断工具,也用于为维修中心建立备件库清单

G.关于增设一个台网台站的设备

1.向中国提供一套包括数据采集系统和不间断电源在内的现有台网类型的设备,安装在拉萨台.

2.该套设备在拉萨安装期间,视需要为中方提供技术协助.

H.关于台网支持

1.SUN 网络支持

为 SUN 台站系统和 SUN 远程通信计算机提供支持.为所需的 SUN 网络的安装,运行和维护提供现场帮助.提供在中国得不到的常规消耗品.

2.IRIS-2 台网和 CDSN 台网支持

继续对现有类型的 CDSN 台站和用 IRIS-2 型改进的北京,兰州,海拉尔,昆明,牡丹江,恩施,琼中和余山地震台提供支持.为在拉萨安装现有类型的 CDSN 仪器提供支持.为在拉萨安装的 IRIS-2 仪器提供支持.继续为北京的数据管理中心和台网维修中心提供支持.为所需的为台网的连续运行和维护提供现场帮助.提供在中国得不到的常规消耗品.

3.数据管理中心维护:

通过签订维修合同尽可能为中心设备提供维护.

四.中方职责

A.SUN 系统的场地准备

1.在四个台站上提供安装 SUN 系统所需要的场地改造,改善

管理和维修中心的设施条件, 诸如增加空间和更好的环境控制, 以便安装 SUN 通讯计算机.

2. 在北京, 兰州, 海拉尔和乌鲁木齐四个台站进行卫星信号强度测试和 RF 噪声试验.

3. 与美方技术人员在新设备的检查, 安装和接收测试方面进行合作.

4. 提供在中国境内的所有仪器的运输.

5. 继续提供包括在北京, 兰州, 海拉尔和乌鲁木齐台的 SUN 系统在内的九个台站的台网日常管理. 继续提供包括在数据管理中心的 SUN 系统在内的数据管理中心和台网维修中心的日常管理.

6. 确保地震数据由北京, 兰州, 海拉尔, 和乌鲁木齐传到北京, 并且由北京传到美国. 提供由于遥测链路技术问题引起的从这四个台传送数据期间所丢失数据的 SUN 系统台带拷贝.

7. 采取任何需要的措施以确保数据管理中心设备每天 24 小时工作所需的供电.

B. 拉萨台 CDSN 系统的场地准备

在拉萨台准备一个新的场地以安装现有 CDSN 类型的台站设备. 包括基本建设, 地震计摆房或山洞建设, 电力扩容, 但不包括提供 UPS 系统.

C. IRIS-2 系统的场地准备:

1. 在九个现有 CDSN 台站上进行必要的改造和改善以准备安装 IRIS-2 系统. 例如, 改善电网供电, 地震噪声的调查和地震计摆房或山洞条件的改善. 对数据管理中心和台网维修中心的设施也进行改善, 例如增加空间和进行较好的环境控制.

2.在昆明台和拉萨台,进行卫星遥测信号的强度测试和在台站进行 RF 噪声测试.

D.与美方技术人员合作,共同对新设备进行调试,安装和验收测试.

E.承担所有设备在中国国内的运输费用.

F.承担台网十个台站,数据管理中心和台网维修中心的日常管理.

G.保证来自北京,兰州,海拉尔,昆明,乌鲁木齐和拉萨(改进后)六个台站的 IRIS-2 系统数据由台站传输到北京并由北京传至美国.上述六个台站因技术问题在传输途径中引起数据丢失,应向美方提供 IRIS-2 系统台站匝带的拷贝.

H.在维修中心安装备用的台站 UPS 系统.

I.采取一切必要步骤确保数据管理中心的电源供应以使数据管理中心设备每天 24 小时工作.

J.如果中方希望由其余牡丹江,恩施,琼中和余山四个改进后的 CDSN 台站将数据传输到管理中心,中方应承担传输费用.中方不必附加任何费用就可用从卫星公司到管理中心已安装的地面链路的剩余容量.

五.建议的执行进度

A. 在 1990 年

在现有 CDSN 系统的北京,兰州,海拉尔和乌鲁木齐台安装 SUN 系统并行运转.在管理中心安装 SUN 远程通信设备,和安装从四个台站到管理中心的遥测链路及从管理中心到美国的遥测链

路.

B.在 1990 年和 1991 年

用 IRIS-2 系统改进昆明,牡丹江,恩施,琼中和余山台.

C.在 1990 年初

改进台网维修中心以管理 SUN 系统和 IRIS-2 系统. 改进数据管理中心以管理来自 SUN 系统和 IRIS-2 系统的数据和编辑 SEED 台网文件.

D.在 1991 年和 1992 年

用 IRIS-2 系统改进北京,兰州,海拉尔,乌鲁木齐和拉萨台.

Box 500, Germantown, MD 20875-0500. See attached Justification			

Part IV - Acceptance Conditions	DOE IA ID No. DE-A101-97-NN20002	
52. General Conditions The Servicing Agency covenants and agrees that it will expeditiously initiate and complete the project for which funds have been awarded under this agreement.		
Special Conditions: A. Patents and Technical Data. Disposition of rights to inventions made in any contract, grant, or cooperative agreement under this Agreement with any small business firm or domestic nonprofit organization will be in accordance with 35 U.S.C. 200-212. In all other contracts, grants, or cooperative agreements under this agreement, the Servicing Agency shall coordinate the disposition of rights to inventions with the DOE Patent Counsel. B. Issue Resolution. Unless otherwise indicated below, it is expected that programmatic guidance will be handled through discussions between the staff of the Servicing Agency's Project Officer listed on the Face Page, item 10 and the DOE Project Officer, Face Page, item 9. Any administrative issues including billing questions, unresolved items or issues requiring a formal change to this Agreement shall be addressed to the DOE Contracting Officer, page 3 of 3, item 54. C. Termination. DOE may terminate this Agreement upon 30 calendar days written notice of such termination addressed to the Servicing Agency. In the event of such termination the Servicing Agency shall be reimbursed, to the extent permitted, for obligations actually incurred to the effective date of the termination and for commitments extending beyond the effective date of termination to a date not later than the date upon which the Agreement would have expired if not terminated under this paragraph, which the Servicing Agency, in the exercise of due diligence, is unable to cancel. Payments under this Agreement, including payments under this article shall not exceed the amount(s) committed under this Agreement. D. Other. Government estimate for the Project Period shown in Block 11 is \$ 81,000		
PART V - OFFER AND ACCEPTANCE		
Note: The agreement/modification must be accepted by the Servicing Agency official in duplicate and one original returned to the party named in item 54. The agreement/modification must be forwarded to the address cited in Item 54 after acceptance signature. Receipt of a written refusal or failure to return the properly executed document will result in rejection of all payment requests to the DOE's Controller's Office.

Statement of Work

To take advantage of Chinese willingness to provide critical seismological data in exchange for visits to the US for (1) training, (2) data and software exchange, and (3) cooperative data interpretation.

To lay the groundwork for US/China cooperation in the monitoring of large chemical explosions to be fired in Western China during the next two years. These events represent targets of opportunity for the calibration of seismic propagation path effects and of the International Monitoring System in and around Western China.

These activities all relate to the monitoring of large chemical explosions in China. However, they are complimented by the data of the Chinese Digital Seismic Network that is operated by the USGS, which is freely available to all parties. The data from these chemical explosions are presently available through the USGS by virtue of a Protocol Agreement (see attached) between the USGS and China that dates back to 1982. This protocol has been renewed every five years, and is subject to an annual USGS/China technical review.

This request will allow the USGS to support FY97 cooperative activities between LANL/LLNL/USGS and the relevant Chinese institutions.

Chinese data (1988/1989 vintage) from large chemical explosions provide critical information regarding seismic wave propagation in China. Newly available are data along a 4,300 km long profile that crosses the entire country in a NW-SE direction, passing near the Chinese test site, Lopnor. These data consist of (1) 7,400 three-component recordings with an average spacing of 2 km, (i.e., 2,150 separate recording sites) and (2) 46 shot points with an average spacing of 90 km, and a charge size of 0.8-3.9 tons. These data were obtained at the cost (to the Chinese) of several million Chinese yuan.

Copies of the digital data are available for evaluation by US investigators. In addition, we will obtain the geographical coordinates and shot times for all of the chemical explosions that were detonated. This information is needed for the purposes of seismic verification and calibration.

These data will be used to develop empirical travel time curves and velocity models for the region. They are anticipated to provide the necessary regionalization information leading to improved location capabilities.

The Chinese (State Seismological Bureau) have announced plans to detonate a series of large (2-4 ton) chemical explosions in Western China over the next two years. These explosions will be recorded by hundreds of Chinese portable seismographs along seismic profiles. The announcement of these large chemical explosions provides a unique opportunity for the staff at the US National Laboratories (LANL and LLNL) to conduct on-site monitoring of seismic, chemical, and electro-magnetic signals associated with these explosions. Signals from the largest of these controlled sources may provide data for the calibration of existing CTBT seismic stations.

FY97 Work Plan

Prof. Yuan Xuecheng and Mr. Wang Youxue will be invited to visit USGS July-September, 1997, to provide the US side with copies of 1988/89 digital data, source coordinates, and the existing Chinese geophysical interpretation. USGS employee Ms. Katharine Favret will devote full time to data transcription and verification, providing the Chinese with USGS seismic data in exchange, and training the Chinese visitors in the use of USGS seismic data processing software.

The USGS Crustal Studies Project in Menlo Park has developed, over a period of 15 years, an extensive array of software programs for the organization, analysis, and interpretation of data from long seismic profiles. The Chinese recognize this, and this is one of the reasons they are willing to share their data with the USGS.

A technical report describing primary information (coordinates of chemical explosions, shot sizes, recorder coordinates, instrument response, and related information) will be prepared by the Chinese and Ms. Favret. Copies of the data will be made available to DOE scientists.

Prof. Wang Chunyong (Project Chief for the Western China Project) will be invited to the USGS in August, 1997, to plan cooperation in the field (on-site recording) for the planned large chemical explosions. It will also be necessary to provide Chinese scientists with copies of USGS seismic data to establish the basis for future exchange of Chinese data. Prof. Wang will travel to Livermore, California and Los Alamos, New Mexico, to discuss project plans with DOE scientists for the Western China project. There are many logistical details to be agreed on for on-site recording by the American side in China (air transport, field vehicles, import of recording equipment, visas, taking data out of the country, etc.).
